CARDIOVASCULAR MEDICINE

TENTH EDITION

BRAUNWALD'S HEART DISEASE

A TEXTBOOK OF
CARDIOVASCULAR MEDICINE

Edited by

Douglas L. Mann, MD

Lewin Chair and Professor of Medicine, Cell Biology, and Physiology
Chief, Division of Cardiology
Washington University School of Medicine in St. Louis
Cardiologist-in-Chief
Barnes-Jewish Hospital
St. Louis, Missouri

Douglas P. Zipes, MD

Distinguished Professor
Professor Emeritus of Medicine, Pharmacology, and Toxicology
Director Emeritus, Division of Cardiology and the Krannert Institute of Cardiology
Indiana University School of Medicine
Indianapolis, Indiana

Peter Libby, MD

Mallinckrodt Professor of Medicine
Harvard Medical School
Chief, Cardiovascular Medicine Division
Brigham and Women's Hospital
Boston, Massachusetts

Robert O. Bonow, MD, MS

Max and Lilly Goldberg Distinguished Professor of Cardiology
Vice Chairman, Department of Medicine
Director, Center for Cardiac Innovation
Northwestern University Feinberg School of Medicine
Chicago, Illinois

Founding Editor and Online Editor

**Eugene Braunwald, MD, MD(Hon),
ScD(Hon), FRCP**

Distinguished Hersey Professor of Medicine
Harvard Medical School
Founding Chairman, TIMI Study Group
Brigham and Women's Hospital
Boston, Massachusetts

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Acknowledgments

Completing a textbook the size and complexity of *Braunwald's Heart Disease* clearly does not occur in a vacuum. The tenth edition owes a great deal to a great many individuals. First and foremost, we would like to thank Dr. Eugene Braunwald for continuing to provide sage counsel at all stages of planning, writing, and editing of this book. We also want to thank the incredibly supportive staff at Elsevier, who enabled the editors to make improvements to the content and visual design of the book as it was being compiled. In this regard, we would like to recognize several Elsevier staff members for their forbearance and indefatigable assistance: Dolores Meloni, executive content strategist, for her boundless energy and enthusiasm for this book; Anne Snyder, senior content development specialist, for everything all of the time; and Louise King, project manager, whose attention to detail and flexibility were measureless.

The editors are also grateful to our colleagues from all over the world who have offered insightful suggestions to improve *Heart Disease*. We particularly wish to acknowledge the following individuals who have provided important feedback on numerous chapters: Shabnam Madadi, MD, Cardiac Imaging Center, Shahid Rajaei Heart Center, Tehran, Iran; Azin Alizadeh Asl, MD, and Anita Sadeghpour, MD, Tabriz University of Medical Sciences and Madani Heart Hospital, Tabriz, Iran; Leili Pourafkari, MD, Razi Hospital, Tabriz, Iran; Banasiak Waldemar, MD, Centre for Heart Disease, Military Hospital, Wroclaw, Poland; Carlos Benjamín Alvarez, MD, PhD, Sacré Coeur Institute, Buenos Aires, Argentina; and Elias B. Hanna, MD, Division of Cardiology, Louisiana State University, New Orleans, Louisiana.

Contributors

**Keith D. Aaronson, MD, MS**

Professor of Internal Medicine, Division of Cardiovascular Medicine, University of Michigan Health System, Ann Arbor, Michigan
Mechanical Circulatory Support

William T. Abraham, MD

Professor of Internal Medicine, Physiology, and Cell Biology, Chair of Excellence in Cardiovascular Medicine, Director, Division of Cardiovascular Medicine, Deputy Director, The Davis Heart and Lung Research Institute, The Ohio State University, Columbus, Ohio
Devices for Monitoring and Managing Heart Failure

Michael A. Acker, MD

Chief, Division of Cardiovascular Surgery, Director, Penn Medicine Heart and Vascular Center, University of Pennsylvania Health System, Philadelphia, Pennsylvania
Surgical Management of Heart Failure

Michael J. Ackerman, MD, PhD

Windland Smith Rice Cardiovascular Genomics Research Professor, Professor of Medicine, Pediatrics, and Pharmacology, Director, Long QT Syndrome/Genetic Heart Rhythm Clinic, Director, Mayo Clinic Windland Smith Rice Sudden Death Genomics Laboratory, Mayo Clinic, Rochester, Minnesota
Genetics of Cardiac Arrhythmias

Elliott M. Antman, MD

Professor of Medicine, Associate Dean for Clinical/Translational Research, Harvard Medical School; Senior Investigator, TIMI Study Group, Brigham and Women's Hospital, Boston, Massachusetts
Critical Evaluation of Clinical Trials

Larry M. Baddour, MD

Professor of Medicine, Mayo Clinic, Rochester, Minnesota
Cardiovascular Infections

Aaron Baggish, MD

Cardiovascular Performance Program, Massachusetts General Hospital; Assistant Professor of Medicine, Harvard Medical School, Boston, Massachusetts
Exercise and Sports Cardiology

C. Noel Bairey Merz, MD

Women's Guild Endowed Chair in Women's Health, Director, Barbara Streisand Women's Heart Center, Director, Preventive Cardiac Center; Director, Linda Joy Pollin Women's Healthy Heart Program; Professor of Medicine, Cedars-Sinai Medical Center, Los Angeles, California
Cardiovascular Disease in Women

Gary J. Balady, MD

Director, Non Invasive Cardiovascular Laboratories, Boston Medical Center; Professor of Medicine, Boston University School of Medicine, Boston, Massachusetts
Exercise Testing

Joshua A. Beckman, MD

Associate Professor of Medicine, Harvard Medical School; Cardiovascular Medicine Division, Brigham and Women's Hospital; Associate Medical Director, VasCore, Massachusetts General Hospital, Boston, Massachusetts
Anesthesia and Noncardiac Surgery in Patients with Heart Disease

Donald M. Bers, PhD

Distinguished Professor and Chair, Pharmacology, University of California Davis, Davis, California
Mechanisms of Cardiac Contraction and Relaxation

Michael A. Bettman, MD

Professor Emeritus of Radiology, Wake Forest University School of Medicine, Winston-Salem, North Carolina
The Chest Radiograph in Cardiovascular Disease

Deepak L. Bhatt, MD, MPH

Senior Investigator, TIMI Study Group, Executive Director, Interventional Cardiovascular Programs, Heart and Vascular Center, Brigham and Women's Hospital; Professor of Medicine, Harvard Medical School, Boston, Massachusetts
Coronary Arteriography and Intracoronary Imaging; Percutaneous Coronary Intervention; Treatment of Noncoronary Obstructive Vascular Disease

William E. Boden, MD

Chief of Medicine, Albany Stratton Veterans Affairs Medical Center; Vice Chairman, Department of Medicine, Albany Medical Center; Professor of Medicine, Albany Medical College, Albany, New York
Stable Ischemic Heart Disease

Robert O. Bonow, MD, MS

Max and Lilly Goldberg Distinguished Professor of Cardiology, Vice Chairman, Department of Medicine, Director, Center for Cardiac Innovation, Northwestern University Feinberg School of Medicine, Chicago, Illinois
Appropriate Use Criteria: Echocardiography; Nuclear Cardiology; Cardiac Catheterization; Appropriate Use Criteria: Multimodality Imaging in Stable Ischemic Heart Disease and Heart Failure; Care of Patients with End-Stage Heart Disease; Valvular Heart Disease; Guidelines: Infective Endocarditis

Eugene Braunwald, MD, MD(Hon), ScD(Hon), FRCP

Distinguished Hersey Professor of Medicine, Harvard Medical School; Founding Chairman, TIMI Study Group, Brigham and Women's Hospital, Boston, Massachusetts
Non-ST Elevation Acute Coronary Syndromes

Alan C. Braverman, MD

Alumni Endowed Professor in Cardiovascular Diseases, Department of Medicine, Washington University School of Medicine in St. Louis, St. Louis, Missouri
Diseases of the Aorta

**J. Douglas Bremner, MD**

Professor of Psychiatry and Radiology, Director, Emory Clinical Neuroscience Research Unit, Emory University School of Medicine; Director, Mental Health Research, Atlanta Veterans Affairs Medical Center, Atlanta, Georgia
Psychiatric and Behavioral Aspects of Cardiovascular Disease

Julie E. Buring, MD

Professor of Medicine, Brigham and Women's Hospital; Professor of Epidemiology, Harvard Medical School; Harvard School of Public Health, Boston, Massachusetts
Risk Markers and the Primary Prevention of Cardiovascular Disease

Hugh G. Calkins, MD

Professor of Medicine, Director, Cardiac Arrhythmia Service, Director, Johns Hopkins Arrhythmogenic Right Ventricular Dysplasia Program, The Johns Hopkins Hospital, Baltimore, Maryland
Hypotension and Syncope

Christopher P. Cannon, MD

Cardiovascular Medicine Division, Brigham and Women's Hospital; Professor of Medicine, Harvard Medical School; Executive Director, Cardiometabolic Trials, Harvard Clinical Research Institute, Boston, Massachusetts
Approach to the Patient with Chest Pain; Non-ST Elevation Acute Coronary Syndromes

John M. Canty, Jr., MD

Albert and Elizabeth Rekate Professor of Medicine, Division of Cardiovascular Medicine, Western New York Veterans Affairs Healthcare System, University at Buffalo, Buffalo, New York
Coronary Blood Flow and Myocardial Ischemia

John D. Carroll, MD

Professor of Medicine, University of Colorado Denver, Denver, Colorado; Director of Interventional Cardiology and Co-Medical Director, Cardiac and Vascular Center, University of Colorado Hospital, Aurora, Colorado
Transcatheter Therapies for Structural Heart Disease in Adults

Augustin Castellanos, MD

Emeritus Professor of Medicine, University of Miami Miller School of Medicine, Miami, Florida
Cardiac Arrest and Sudden Cardiac Death

Ming Hui Chen, MD, MSc

Boston Children's Hospital and Dana Farber Cancer Institute, Director, Cardiovascular Health for Cancer Survivors; Assistant Professor of Medicine, Harvard Medical School, Boston, Massachusetts
Cardiovascular Complications of Cancer Therapeutic Agents

Leslie T. Cooper, Jr., MD

Director, Gonda Vascular Center, Mayo Clinic, Rochester, Minnesota
Myocarditis

Mark A. Creager, MD

Director, Vascular Center, Brigham and Women's Hospital; Simon C. Fireman Scholar in Cardiovascular Medicine, Professor of Medicine, Harvard Medical School, Boston, Massachusetts
Peripheral Artery Diseases

Charles J. Davidson, MD

Chief, Clinical Cardiology, Medical Director, Bluhm Cardiovascular Institute, Northwestern Memorial Hospital; Professor of Medicine, Northwestern University Feinberg School of Medicine, Chicago, Illinois
Cardiac Catheterization

Stephen Devries, MD

Executive Director, Gaples Institute for Integrative Cardiology, Deerfield, Illinois; Associate Professor of Medicine, Division of Cardiology, Northwestern University, Chicago, Illinois
Integrative Approaches to the Management of Patients with Heart Disease

Neal W. Dickert, MD, PhD

Assistant Professor, Department of Medicine, Division of Cardiology, School of Medicine, Department of Epidemiology, Rollins School of Public Health, Emory University, Atlanta, Georgia
Ethics in Cardiovascular Medicine

Vasken Dilsizian, MD

Professor of Medicine and Radiology, University of Maryland School of Medicine; Chief, Division of Nuclear Medicine, University of Maryland Medical Center, Baltimore, Maryland
Nuclear Cardiology; Appropriate Use Criteria: Multimodality Imaging in Ischemic Heart Disease and Heart Failure

Dirk J. Duncker, MD, PhD

Professor of Experimental Cardiology, Department of Cardiology, Erasmus University Medical Center, Rotterdam, The Netherlands
Coronary Blood Flow and Myocardial Ischemia

Ezekiel J. Emanuel, MD, PhD

Vice Provost for Global Initiatives, Diane V.S. Levy and Robert M. Levy University Professor, Chairperson, Department of Medical Ethics and Health Policy, University of Pennsylvania, Philadelphia, Pennsylvania
Ethics in Cardiovascular Medicine

Rodney H. Falk, MD

Director, Cardiac Amyloidosis Program, Brigham and Women's Hospital; Associate Clinical Professor of Medicine, Harvard Medical School, Boston, Massachusetts
The Dilated, Restrictive, and Infiltrative Cardiomyopathies

James C. Fang, MD

Professor of Medicine, Chief, Division of Cardiovascular Medicine, Executive Director, Cardiovascular Service Line, University of Utah Health Sciences Center, Salt Lake City, Utah
The History and Physical Examination: An Evidence-Based Approach

G. Michael Felker, MD, MHS

Associate Professor of Medicine, Division of Cardiology, Duke University School of Medicine, Durham, North Carolina
Diagnosis and Management of Acute Heart Failure

Stacy D. Fisher, MD

Director of Women's and Complex Heart Diseases, Medicine, Cardiology, and Pediatric Cardiology, University of Maryland Comprehensive Heart Center, Baltimore, Maryland
Cardiovascular Abnormalities in HIV-Infected Individuals

Lee A. Fleisher, MD

Robert D. Dripps Professor and Chair, Anesthesiology and Critical Care, Professor of Medicine, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, Pennsylvania
Anesthesia and Noncardiac Surgery in Patients with Heart Disease

Thomas Force, MD

Professor of Medicine, Division of Cardiovascular Medicine, Vanderbilt University School of Medicine, Nashville, Tennessee
Cardiovascular Complications of Cancer Therapeutic Agents

William K. Freeman, MD

Professor of Medicine, Mayo Clinic College of Medicine,
Rochester, Minnesota
Cardiovascular Infections

J. Michael Gaziano, MD, MPH

Chief, Division of Aging, Brigham and Women's Hospital; Scientific
Director, Massachusetts Veterans Epidemiology Research and
Information Center, Veterans Administration Boston Healthcare
System; Professor of Medicine, Harvard Medical School, Boston,
Massachusetts
Global Burden of Cardiovascular Disease

Thomas A. Gaziano, MD, MSc

Assistant Professor, Harvard Medical School; Cardiovascular
Medicine Division, Brigham and Women's Hospital, Boston,
Massachusetts
Global Burden of Cardiovascular Disease

Jacques Genest, MD

Professor of Medicine, Cardiology, McGill University; Scientific
Director, Centre for Innovative Medicine, McGill University Health
Centre, Montreal, Quebec, Canada
Lipoprotein Disorders and Cardiovascular Disease

Robert E. Gerszten, MD

Director of Clinical and Translational Research, Massachusetts
General Hospital Institute for Heart, Vascular, and Stroke Care;
Professor of Medicine, Harvard Medical School; Senior Associate
Member, Broad Institute, Boston, Massachusetts
*Biomarkers, Proteomics, Metabolomics, and Personalized
Medicine*

Linda Gillam, MD, MPH

Chairperson, Department of Cardiovascular Medicine, Morristown
Medical Center, Atlantic Health System, Morristown, New Jersey
Echocardiography

Geoffrey S. Ginsburg, MD, PhD

Executive Director, Center for Personalized and Precision Medicine,
Duke University Health Systems; Director, Genomic Medicine,
Institute for Genome Sciences and Policy, Professor of Medicine,
Pathology and Biomedical Engineering, Duke University School
of Medicine, Durham, North Carolina
Personalized and Precision Cardiovascular Medicine

Robert P. Giugliano, MD, SM

Physician, Cardiovascular Medicine Division, Brigham and
Women's Hospital; Associate Professor of Medicine, Harvard
Medical School, Boston, Massachusetts
Non-ST Elevation Acute Coronary Syndromes

Ary L. Goldberger, MD

Professor of Medicine, Harvard Medical School; Director, Margret
and H.A. Rey Institute for Nonlinear Dynamics in Medicine;
Associate Chief, Interdisciplinary Medicine and Biotechnology,
Beth Israel Deaconess Medical Center, Boston, Massachusetts
Electrocardiography

Samuel Z. Goldhaber, MD

Professor of Medicine, Harvard Medical School; Director,
Thrombosis Research Group; Senior Staff Physician,
Cardiovascular Medicine Division, Brigham and Women's
Hospital, Boston, Massachusetts
Pulmonary Embolism

Larry B. Goldstein, MD

Professor of Neurology and Director, Duke Stroke Center, Duke
University; Staff Neurologist, Durham Veterans Affairs Medical
Center, Durham, North Carolina
Prevention and Management of Ischemic Stroke

Sarah J. Goodlin, MD

Chief, Geriatrics, Portland Veterans Affairs Medical Center;
Associate Professor, Oregon Health and Science University,
Portland, Oregon
Care of Patients with End-Stage Heart Disease

William J. Groh, MD, MPH

Associate Professor of Medicine, Indiana University School of
Medicine, Indianapolis, Indiana
Neurologic Disorders and Cardiovascular Disease

Martha Gulati, MD, MS

Associate Professor of Medicine, Division of Cardiology, Associate
Professor of Clinical Public Health, Division of Epidemiology,
Sarah Ross Soter Chair, Women's Cardiovascular Health, Section
Director, Preventive Cardiology and Women's Cardiovascular
Health, The Ohio State University Wexner Medical Center,
Columbus, Ohio
Cardiovascular Disease in Women

Roger J. Hajjar, MD

Director, Cardiovascular Research Center, Icahn School of
Medicine at Mount Sinai, New York, New York
Cardiovascular Regeneration and Gene Therapy

Joshua M. Hare, MD

Louis Lemberg Professor of Medicine, Cardiovascular Division,
Director, Interdisciplinary Stem Cell Institute, University of Miami
Miller School of Medicine, Miami, Florida
Cardiovascular Regeneration and Gene Therapy

Gerd Hasenfuss, MD

Professor of Medicine, Chair, Department of Cardiology and
Pneumology, Chair, Heart Center, University of Goettingen;
Chair, Heart Research Center, DZHK (German Center of
Cardiovascular Research), Goettingen, Germany
Pathophysiology of Heart Failure

Ray E. Hershberger, MD

Professor of Medicine, Director, Division of Human Genetics,
Division of Cardiovascular Medicine, Section of Heart Failure
and Cardiac Transplantation, The Ohio State University Wexner
Medical Center, Columbus, Ohio
The Dilated, Restrictive, and Infiltrative Cardiomyopathies

L. David Hillis, MD

Professor and Chair, Internal Medicine, The University of Texas
Health Science Center, San Antonio, Texas
Chemical Cardiomyopathies

William E. Hopkins, MD

Associate Professor of Medicine, The University of Vermont;
Attending Cardiologist, Fletcher Allen Health Care, Burlington,
Vermont
Pericardial Diseases

Marc Humbert, MD, PhD

Professor of Respiratory Medicine, Service de Pneumologie, Hôpital
Bicêtre; Assistance, Publique Hôpitaux de Paris, Université
Paris-Sud, Paris, France
Pulmonary Hypertension

James L. Januzzi, Jr., MD

Professor of Medicine, Harvard Medical School; Roman W.
De Sanctis Endowed Distinguished Clinical Scholar, Division of
Cardiology, Massachusetts General Hospital, Boston,
Massachusetts
Clinical Assessment of Heart Failure

**Mariell Jessup, MD**

Associate Chief, Clinical Affairs, Division of Cardiovascular Medicine, Professor of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania
Surgical Management of Heart Failure

Sekar Kathiresan, MD

Associate Member, Broad Institute, Cambridge, Massachusetts; Associate Professor of Medicine, Harvard Medical School; Director, Preventive Cardiology, Massachusetts General Hospital, Boston, Massachusetts
Principles of Cardiovascular Genetics

Scott Kinlay, PhD

Director, Cardiac Catheterization Laboratory and Vascular Medicine, Veterans Affairs Boston Healthcare System, West Roxbury, Massachusetts; Co-Director, Vascular Diagnostic and Interventional Clinical and Research Program, Veterans Affairs Boston, Brigham and Women's Hospital; Associate Professor in Medicine, Harvard Medical School, Boston, Massachusetts
Coronary Arteriography and Intracoronary Imaging; Treatment of Noncoronary Obstructive Vascular Disease

Irwin Klein, MD

Professor of Medicine, New York University School of Medicine, New York, New York
Endocrine Disorders and Cardiovascular Disease

Kirk U. Knowlton, MD

Professor of Medicine, Division of Cardiology, Department of Medicine, University of California San Diego, La Jolla, California
Myocarditis

Harlan M. Krumholz, MD, SM

Harold H. Hines, Jr. Professor of Medicine, Epidemiology, and Public Health, Section of Cardiovascular Medicine and Robert Wood Johnson Foundation Clinical Scholars Program, Department of Medicine, Department of Health Policy and Management, School of Public Health, Yale University; Center for Outcomes Research and Evaluation, Yale-New Haven Hospital, New Haven, Connecticut
Clinical Decision Making in Cardiology

Raymond Y. Kwong, MD, MPH

Associate Professor of Medicine, Harvard Medical School; Director of Cardiac Magnetic Resonance Imaging, Cardiovascular Medicine Division, Brigham and Women's Hospital, Boston, Massachusetts
Cardiovascular Magnetic Resonance Imaging

Richard A. Lange, MD, MBA

Founding President and Dean, Paul L. Foster School of Medicine, Texas Tech University Health Sciences Center at El Paso, El Paso, Texas
Chemical Cardiomyopathies

Thomas H. Lee, MD

Chief Medical Officer, Press Ganey, Boston, Massachusetts
Guidelines: Pregnancy and Heart Disease

Daniel J. Lenihan, MD

Professor of Medicine, Division of Cardiovascular Medicine, Vanderbilt University, Nashville, Tennessee
Tumors Affecting the Cardiovascular System

Martin M. LeWinter, MD

Professor of Medicine and Molecular Physiology and Biophysics, Attending Physician, Cardiology, Fletcher Allen Health Care, Burlington, Vermont
Pericardial Diseases

Peter Libby, MD

Mallinckrodt Professor of Medicine, Harvard Medical School; Chief, Cardiovascular Medicine Division, Brigham and Women's Hospital, Boston, Massachusetts
Biomarkers, Proteomics, Metabolomics, and Personalized Medicine; The Vascular Biology of Atherosclerosis; Risk Markers and the Primary Prevention of Cardiovascular Disease; Systemic Hypertension: Management; Lipoprotein Disorders and Cardiovascular Disease; Peripheral Artery Diseases

Steven E. Lipshultz, MD

Schotanus Family Endowed Chair of Pediatrics, Professor and Chair, Carmen and Ann Adams Department of Pediatrics, Wayne State University School of Medicine; President, University Pediatricians; Pediatrician-in-Chief, Children's Hospital of Michigan, Detroit, Michigan
Cardiovascular Abnormalities in HIV-Infected Individuals

William C. Little, MD

Lehan Professor of Cardiology, Chair, Department of Medicine, University of Mississippi Medical Center, Jackson, Mississippi
Heart Failure with a Preserved Ejection Fraction

Douglas L. Mann, MD

Lewin Chair and Professor of Medicine, Cell Biology, and Physiology, Chief, Division of Cardiology, Washington University School of Medicine in St. Louis; Cardiologist-in-Chief, Barnes-Jewish Hospital, St. Louis, Missouri

Preface to the Tenth Edition

The editors are pleased to present the tenth edition of *Braunwald's Heart Disease* as the latest update of a unique learning platform that aims to provide practitioners, physicians-in-training, and students at all levels with the critical tools to keep abreast of the rapidly changing scientific foundations and clinical advances in cardiovascular medicine. *Heart Disease* has been developed as a “living textbook” that will provide readers with the latest updates in the field in real time. To this end, the print version of the tenth edition, which has been revised extensively, is complemented by a new online version that is not only visually spectacular, but also contains audio, video, and additional written content not available in the textbook. Icons are placed strategically in the margins of the text of the print version to guide readers to the appropriate related online materials. In keeping with the rapid pace of advances in the field of cardiovascular medicine, the online version of *Heart Disease* is updated frequently with the results of late-breaking clinical trials, reviews of important new research publications, and updates on clinical practice authored by leaders in the field. These online supplements are selected and edited masterfully by Dr. Eugene Braunwald.

In preparing the preface for the tenth edition, we thought it appropriate to reflect back upon the prescient guiding principles that were articulated by Dr. Braunwald, in his Preface to the first edition of *Heart Disease* (1980).

“An attempt to summarize our present understanding of heart disease in a comprehensive textbook for the serious student of this subject is a formidable undertaking. A single text—even a long one—cannot adequately cover every aspect of a subject as extensive as heart disease. Since the early part of this century, clinical cardiology has had a particularly strong foundation in the basic sciences of physiology and pharmacology. More recently, the disciplines of molecular biology, genetics, developmental biology, biophysics, biochemistry, experimental pathology, and bioengineering have also begun to provide critically important information about cardiac function and malfunction. Although it was decided that Heart Disease was to be primarily a clinical treatise and not a textbook of fundamental cardiovascular science, an effort has been made to explain, in some detail, the scientific basis of cardiovascular diseases. To achieve this objective, the sciences fundamental to heart disease are in most cases presented in the chapters describing the various disease states and their treatment rather than in separate chapters. Although it is recognized that cardiovascular surgery has had an enormous impact on the management of patients with heart disease, the major emphasis in this book is on the rationale and indications for cardiac operations rather than on operative techniques per se.”

The tenth edition of *Braunwald's Heart Disease* hews closely to the traditions established by the first and each subsequent edition of *Heart Disease*, by covering the entire spectrum of cardiovascular medicine, highlighting the latest advances in basic, translational, and clinical science, with an emphasis on conveying succinctly how this information informs both the prevention and the treatment, of cardiovascular disease. Twenty-seven of the 89 chapters in this edition are new, including three chapters covering topics that were not addressed in prior editions. We include 53 new authors, all of whom are highly accomplished and recognized in their respective disciplines. All chapters carried over from the ninth edition have been thoroughly updated and extensively revised. The tenth edition includes nearly 2600 figures, most of which are in full color, as well

as 600 tables. Moreover, the online content has been enhanced with 240 videos. As with previous editions, the tenth edition contains 21 updated practice guides, seven entirely new guidelines not in the ninth edition, and six appropriate use criteria, two of which are entirely new.

A detailed accounting of all of the changes in the new edition is not feasible within the narrow confines of this Preface. However, the editors would like to highlight several of the exciting changes in the tenth edition, beginning with an entirely new section on genetics and personalized medicine (Part II), which includes a chapter providing an overview of personalized cardiovascular medicine, followed by chapters on principles of cardiovascular genetics and drug therapeutics. A new chapter on biomarkers provides background and guidance on their use, development, and validation as clinically useful tools. The section on evaluation of the patient (Part III) has completely new chapters on echocardiography and exercise stress testing. Given the rapid advances in the field of heart failure, Part IV has been revised substantially, with new chapters and guidelines on the clinical assessment of heart failure, including the latest recommendations on biomarkers, the diagnosis and management of acute heart failure, and heart failure with a preserved ejection fraction, as well as the emerging area of cardiovascular regeneration and gene therapy. Part V, on arrhythmias, sudden death, and syncope has been updated and revised with chapters that review the remarkable advances in this discipline. The section on preventive cardiology (Part VI) features a new omnibus chapter on risk factors and the prevention of cardiovascular disease and a new chapter on comprehensive cardiac rehabilitation and the treatment of hypertension. Part VII focuses on atherosclerotic cardiovascular disease and includes new guidelines for percutaneous intervention and stable ischemic heart disease. There are new chapters on quality of care, cardiovascular disease in women, exercise and sports cardiology, integrated medicine, ethics, cardiooncology, perioperative management in non-cardiac and cardiac surgery, cardiovascular infections, and pulmonary hypertension (including new international guidelines). There are also important revised chapters on interventions for structural heart disease and valvular heart disease, including new guidelines for this important area. In recognition of the importance of genetics and the emerging role of personalized medicine, discussions of the genetic basis of specific diseases are now incorporated within the relevant chapters, rather than in separate chapters.

As noted at the outset, *Braunwald's Heart Disease* is the centerpiece of a much broader learning platform that includes a growing family of *Braunwald's Heart Disease* companion texts, which continues to expand and provide detailed expert content for the subspecialist across a broad range of cardiovascular conditions. These include: *Clinical Lipidology*, edited by Christie Ballantyne; *Clinical Arrhythmology and Electrophysiology*, authored by Ziad Issa, John Miller, and Douglas Zipes; *Diabetes in Cardiovascular Disease*, by Darren McGuire and Nikolaus Marx; *Heart Failure*, edited by Douglas L. Mann and Michael Felker; *Valvular Heart Disease*, by Catherine Otto and Robert Bonow; *Acute Coronary Syndromes*, by Pierre Thérioux; *Preventive Cardiology*, by Roger Blumenthal, JoAnne Foody, and Nathan Wong; *Mechanical Circulatory Support*, by Robert Kormos and Leslie Miller; *Hypertension*, by Henry Black and William Elliott; *Cardiovascular Therapeutics*, by Elliott Antman and Marc Sabatine; and *Vascular Medicine*, by Mark Creager, Joshua Beckman, and Joseph Loscalzo. Additional companion texts will be forthcoming shortly, including *Cardiovascular Interventions* by Deepak Bhatt. Each of the companion texts, as well as *Heart Disease*, is complemented by an updated online version. As with previous editions

of *Heart Disease*, Dr. Leonard S. Lilly's *Braunwald's Heart Disease Review and Assessment* is available. There are also recent atlases on cardiovascular imaging, such as *Cardiovascular Magnetic Resonance* by Christopher Kramer and Gregory Hundley, *Cardiovascular Computed Tomography* by Allen Taylor, and *Nuclear Cardiology* by Ami Iskandrian and Ernest Garcia. Readers of *Heart Disease* can turn to the companions as a convenient source of information that follows the same guiding principles as the parent text.

The extent to which the tenth edition of *Braunwald's Heart Disease* proves useful to those who seek to broaden their knowledge base in an effort to improve outcomes for patients afflicted with

cardiovascular disease is a direct reflection of the many talented and dedicated individuals involved in the preparation of this edition. Without question, this book could not have become a reality were it not for their expertise, scholarship, and unswerving commitment to maintaining the standards of excellence established by Dr. Braunwald with the first edition.

Preface—Adapted from the First Edition

Cardiovascular disease is the greatest scourge affecting the industrialized nations. As with previous scourges—bubonic plague, yellow fever, and smallpox—cardiovascular disease not only strikes down a significant fraction of the population without warning but also causes prolonged suffering and disability in an even larger number. In the United States alone, despite recent encouraging declines, cardiovascular disease is still responsible for almost 1 million fatalities each year and more than half of all deaths; almost 5 million persons afflicted with cardiovascular disease are hospitalized each year. The cost of these diseases in terms of human suffering and material resources is almost incalculable. Fortunately, research focusing on the causes, diagnosis, treatment, and prevention of heart disease is moving ahead rapidly.

To provide a comprehensive, authoritative text in a field that has become as broad and deep as cardiovascular medicine, I chose to enlist the aid of a number of able colleagues. However, I hoped that my personal involvement in the writing of about half of the book

would make it possible to minimize the fragmentation, gaps, inconsistencies, organizational difficulties, and impersonal tone that sometimes plague multiauthored texts.

Since the early part of the twentieth century, clinical cardiology has had a particularly strong foundation in the basic sciences of physiology and pharmacology. More recently, the disciplines of molecular biology, genetics, developmental biology, biophysics, biochemistry, experimental pathology, and bioengineering have also begun to provide critically important information about cardiac function and malfunction. Although *Heart Disease: A Textbook of Cardiovascular Medicine* is primarily a clinical treatise and not a textbook of fundamental cardiovascular science, an effort has been made to explain, in some detail, the scientific bases of cardiovascular diseases.

Eugene Braunwald

Video Contents

11 The History and Physical Examination: An Evidence-Based Approach 95

- 11-1 V wave
- 11-2 Kussmaul sign
- 11-3 Precordial diastolic gallop

16 Nuclear Cardiology 271

- 16-1 FDG PET imaging
- 16-2 Rubidium PET imaging

17 Cardiovascular Magnetic Resonance Imaging 320

- 17-1 Cine CMR imaging of myocardial infarction (MI) complications
- 17-2 Simultaneous high-resolution imaging of myocardial infarction and coronary stenosis in a 48-year-old man with three-vessel coronary artery disease
- 17-3 CMR imaging of ischemia and infarct extent
- 17-4 Quantitation of myocardial iron content
- 17-5 Myocardial rupture after acute inferior myocardial infarction in a 56-year-old man who presented with ventricular fibrillation
- 17-6 Severe left anterior descending arterial stenosis
- 17-7 Mitral valve anomaly in hypertrophic cardiomyopathy
- 17-8 Microvascular dysfunction in a patient with hypertrophic cardiomyopathy
- 17-9 Ventricular tachycardia and syncope
- 17-10 Takotsubo cardiomyopathy
- 17-11 Chronic constrictive pericarditis with pericardial adhesions post radiation
- 17-12 Vector flow lines in the normal aorta
- 17-13 Abnormal flow patterns
- 17-14 Cine imaging of a patient with a large mass attached to the mitral valve before and after contrast was injected

18 Cardiac Computed Tomography 341

- 18-1 Normal CT ventriculogram
- 18-2 Ventriculogram in a patient with mitral valve prolapse and mitral annular calcification
- 18-3 Ventriculogram in a patient with combined aortic and mitral regurgitation

19 Cardiac Catheterization 364

- 19-1 Right heart catheterization
- 19-2 Radial artery catheterization

33 Genesis of Cardiac Arrhythmias: Electrophysiologic Considerations 629

- 33-1 Simulation of anterograde conduction through the AVN
- 33-2 Two-dimensional confocal imaging of subsarcolemmal calcium events

33-3 Simulation of fast-slow reentry using an electroanatomical model

33-4 Simulation of electrical reentry in a three-dimensional model of the infarct border zone

33-5 Posterior left atrial activation during atrial fibrillation

33-6 Spiral wave activity

34 Diagnosis of Cardiac Arrhythmias 662

34-1 Focal atrial tachycardia

34-2 Macroreentrant atrial tachycardia following atrial fibrillation ablation

35 Therapy for Cardiac Arrhythmias 685

35-1 Macroreentrant left atrial tachycardia after pulmonary vein isolation

35-2 Macroreentrant left atrial tachycardia after pulmonary vein isolation in the same patient as in Video 35-1

38 Atrial Fibrillation: Clinical Features, Mechanisms, and Management 798

38-1 Pulmonary vein isolation using image integration

55 Percutaneous Coronary Intervention 1245

55-1 Contrast injected into the pericardium

55-2 Air injected into the right coronary artery

56 Transcatheter Therapies for Structural Heart Disease in Adults 1269

56-1 Left atrial appendage closure

56-2 Aortic paravalvular leak closure

56-3 Paravalvular leak closure

56-4 Transcatheter aortic balloon-expandable valve implantation

56-5 Percutaneous aortic valve implantation using a 14F sheath

56-6 Transcatheter aortic CoreValve implantation

56-7 Mitral valvuloplasty

56-8 Pulmonary percutaneous valve implantation

56-9 Fluoroscopic images of valve implantation in failed mitral valve

56-10 Balloon-expandable valve implantation in failed mitral valve

56-11 Balloon-expandable valve implantation in all four failed valves

57 Diseases of the Aorta 1277

57-1 Echocardiogram of a patient with Marfan syndrome demonstrating dilation of the aortic root and mitral valve prolapse

57-2 Parasternal short-axis view echocardiogram demonstrating dilated sinuses of Valsalva in a young patient with Marfan syndrome

57-3 Echocardiogram demonstrating a markedly dilated aortic root and ascending aorta

57-4 Transesophageal echocardiogram demonstrating a dilated aortic root and ascending aorta and acute type A aortic dissection

57-5 Color-flow Doppler of the same patient in Video 57-3 with acute type A aortic dissection, demonstrating severe aortic regurgitation due to malcoaptation of the aortic valve leaflets and intimal flap prolapse interfering with aortic valve function

57-6 Transesophageal echocardiogram demonstrating ascending aortic dissection

57-7 Transesophageal echocardiogram color-flow imaging demonstrating acute ascending aortic dissection with prolapse of the dissection flap into the left ventricular outflow tract, leading to severe aortic regurgitation

57-8 Transesophageal echocardiogram demonstrating acute type A aortic dissection with mobile intimal flap just distal to the aortic valve

57-9 Transesophageal echocardiogram of a woman with Marfan syndrome and acute type A aortic dissection occurring during the 28th week of pregnancy

57-10 Transthoracic echocardiogram parasternal long axis view of a type A aortic dissection.

57-11 Transthoracic echocardiogram of acute type A aortic dissection in the setting of a markedly dilated ascending aortic aneurysm

57-12 Transthoracic echocardiogram, subcostal view, in a patient with chest pain demonstrating an acute aortic dissection

57-13 Transthoracic echocardiogram demonstrating hemopericardium in a patient with unexplained hypotension

57-14 Transesophageal echocardiogram demonstrating an intimal tear in the dissection flap in a patient with acute descending aortic dissection

57-15 Coronary angiogram of a patient with acute chest pain and ST-segment depressions

57-16 Left main coronary injection of the same patient with acute type A aortic dissection depicted in Video 57-14

57-17 Aortogram of the patient depicted in Videos 57-14 and 57-15 demonstrating acute type A dissection

57-18 Transesophageal echocardiogram of an intramural hematoma of the aorta

60 Treatment of Noncoronary Obstructive Vascular Disease 1347

60-1 Diagnostic angiography

60-2 Distal superficial femoral artery

60-3 Wire advancement through the superficial femoral artery

60-4 Percutaneous transluminal angioplasty of the superficial femoral artery

60-5 Angiography following percutaneous transluminal angioplasty

60-6 Angiography following first stent insertion

60-7 Angiography of the more proximal lesion

60-8 Angiography following second stent insertion

60-9 Post-stent dilation angiography

60-10 Post-stent angiography

62 Congenital Heart Disease 1391

62-1 Anomalous origin of the left coronary artery from the pulmonary artery

62-2 Anomalous origin of the left coronary artery from the pulmonary artery

62-3 Anomalous left coronary artery originating from the right pulmonary artery

62-4 Scimitar syndrome

62-5 Scimitar syndrome

62-6 Parachute mitral valve

62-7 Tricuspid atresia and dextrocardia

62-8 Normal heart

62-9 Atrioventricular discordance

62-10 Atrioventricular and ventriculoarterial discordance

62-11 Double inlet left ventricle

62-12 Double inlet left ventricle

62-13 Double inlet left ventricle

62-14 Double inlet left ventricle

62-15 Double inlet left ventricle

62-16 Double inlet left ventricle

62-17 Double inlet right ventricle

62-18 Double inlet ventricle with common atrium and common atrioventricular valve

62-19 Hypoplastic posterior left ventricle

62-20 Superior-inferior ventricles and crisscross heart

62-21 Ventricular inversion with a common atrioventricular valve and an ostium prima defect

62-22 Tricuspid atresia

62-23 Tricuspid atresia

62-24 Hypoplastic right ventricle

62-25 Hypoplastic left heart syndrome

62-26 Repaired common atrioventricular valve

62-27 Repaired common atrioventricular valve

62-28 Three-dimensional echocardiography of a tricuspid valve, with a hypoplastic mitral valve

62-29 Coronary sinus defect

62-30 Coronary sinus defect

62-31 Sinus venosus defect

62-32 Sinus venosus defect

62-33 Amplatzer closure of secundum atrial septal defect

62-34 Cause and treatment of platypnea/orthodeoxia syndrome

62-35 Three-dimensional echocardiography of cleft mitral leaflet

62-36 Primum atrial defect

62-37 Primum atrial defect

62-38 Regurgitant left atrioventricular valve in a primum atrial defect

62-39 Unbalanced atrioventricular septal defect

62-40 Unbalanced atrioventricular septal defect

- 62-41** Unbalanced atrioventricular septal defect
- 62-42** Doubly committed subarterial ventricular septal defect
- 62-43** Doubly committed subarterial ventricular septal defect
- 62-44** Doubly committed subarterial ventricular septal defect
- 62-45** Large perimembranous inlet ventricular septal defect
- 62-46** Large perimembranous inlet ventricular septal defect
- 62-47** Perimembranous ventricular septal defect with right ventricular muscle bundles and a small subaortic ridge
- 62-48** Perimembranous ventricular septal defect with right ventricular muscle bundles and a small subaortic ridge
- 62-49** Perimembranous ventricular septal defect with right ventricular muscle bundles and a small subaortic ridge
- 62-50** Perimembranous ventricular septal defect with right ventricular muscle bundles
- 62-51** Perimembranous ventricular septal defect with right ventricular muscle bundles
- 62-52** Stenotic homograft conduit with stent therapy
- 62-53** Radiofrequency-assisted balloon dilation of the atretic pulmonary valve
- 62-54** Calcified homograft conduit with potential coronary compression
- 62-55** Melody valve placement in a stenotic homograft conduit
- 62-56** Catheter management of a troubled Fontan circulation
- 62-57** Interventional and thrombolytic management of thrombosis in a Fontan patient
- 62-58** Catheter management of a stenotic left pulmonary artery in a Fontan patient
- 62-59** Stent management of a kinked Fontan connection
- 62-60** Senning atrial baffles
- 62-61** Senning atrial baffles
- 62-62** Atrial switch and superior systemic venous baffle
- 62-63** Palliative Senning procedure
- 62-64** Systemic tricuspid valve coaptation after Senning procedure
- 62-65** Repaired atrial ventricular septal defect and narrowed left ventricular outflow tract
- 62-66** Repaired atrial ventricular septal defect and associated aortic regurgitation
- 62-67** Rastelli repair of tricuspid valve regurgitation shows moderate tricuspid regurgitation
- 62-68** Moderate systemic tricuspid regurgitation after Senning procedure
- 62-69** Systemic tricuspid regurgitation after Senning procedure
- 62-70** Three-dimensional echocardiography of a systemic tricuspid valve after Senning procedure
- 62-71** Interventional therapy of mustard baffle stenosis and leakage
- 62-72** Poor tricuspid leaflet coaptation
- 62-73** Three-dimensional echocardiography of tricuspid regurgitation
- 62-74** Transesophageal echocardiography of tricuspid regurgitation
- 62-75** Abnormal systemic tricuspid valve in congenitally corrected transposition of the great arteries
- 62-76** Abnormal tricuspid valve in congenitally corrected transposition of the great arteries
- 62-77** Three-dimensional echocardiography of abnormal tricuspid valve in congenitally corrected transposition of the great arteries
- 62-78** Three-dimensional echocardiography of abnormal tricuspid valve in congenitally corrected transposition of the great arteries
- 62-79** Three-dimensional echocardiography of tricuspid regurgitation in congenitally corrected transposition of the great arteries
- 62-80** Severe tricuspid regurgitation in congenitally corrected transposition of the great arteries
- 62-81** Ebstein anomaly
- 62-82** Ebstein anomaly
- 62-83** Three-dimensional echocardiography of Ebstein tricuspid valve
- 62-84** Stent management of hypoplastic aortic arch
- 62-85** Stent management of adult aortic coarctation
- 62-86** Stent management of complex coarctation repair
- 62-87** Stent management of aortic coarctation
- 62-88** Balloon dilation of critical neonatal aortic stenosis
- 62-89** Fibromuscular subaortic stenosis
- 62-90** Tunnel subaortic stenosis
- 62-91** Three-dimensional echocardiography of fibromuscular subaortic stenosis
- 62-92** Transesophageal echocardiography of congenital mitral stenosis
- 62-93** Transesophageal echocardiography of congenital mitral stenosis and fibromuscular subaortic stenosis
- 62-94** Cleft anterior leaflet
- 62-95** Cleft anterior leaflet
- 62-96** Three-dimensional echocardiography of isolated mitral cleft
- 62-97** Muscular inlet ventricular septal defect
- 62-98** Double orifice mitral valve
- 62-99** Three-dimensional echocardiography double orifice mitral valve
- 62-100** Valvular pulmonary stenosis
- 62-101** Valvular pulmonary stenosis
- 62-102** Catheter management of neonatal pulmonary atresia with intact ventricular septum
- 62-103** Dysplastic pulmonary valve stenosis
- 62-104** Cor triatriatum
- 62-105** Cor triatriatum
- 62-106** Cor triatriatum
- 62-107** Anomalous pulmonary venous drainage in an elderly man
- 62-108** Catheter management of a large circumflex artery fistula to the left ventricle

**63 Valvular Heart Disease 1446**

- 63-1** Level of outflow obstruction
- 63-2** Left ventricular dilation and increased sphericity with chronic severe aortic regurgitation
- 63-3** Mild aortic regurgitation
- 63-4** Vena contracta measurements
- 63-5** Imaging findings in severe aortic regurgitation
- 63-6** Severe aortic regurgitation
- 63-7** Transesophageal echocardiography of a stenotic bicuspid aortic valve
- 63-8** Bicuspid aortic valve
- 63-9** Mild rheumatic mitral stenosis
- 63-10** Planimetry of mitral valve area
- 63-11** Mitral stenosis jet on color-flow Doppler imaging
- 63-12** Three-dimensional transesophageal echocardiography of mitral stenosis
- 63-13** Spontaneous left atrial contrast
- 63-14** Transesophageal echocardiography-guided balloon mitral commissurotomy
- 63-15** Mitral valve morphology
- 63-16** Normal mitral regurgitation
- 63-17** Flail mitral valve leaflet
- 63-18** Anteriorly directed mitral regurgitation on transesophageal echocardiography
- 63-19** Posteriorly directed mitral regurgitation on transesophageal echocardiography

63-20 Multiple mitral regurgitation jets on transesophageal echocardiography

63-21 Three-dimensional image of a mitral valve

63-22 Secondary mitral regurgitation

63-23 Proximal isovelocity surface area (PISA) imaging

63-24 Mitral valve prolapse

63-25 Late systolic mitral valve prolapse

63-26 Severe tricuspid regurgitation

63-27 Trace pulmonic valve regurgitation

70 Cardiovascular Abnormalities in HIV-Infected Individuals 1624

70-1 Cardiovascular abnormalities in HIV-infected individuals

71 Pericardial Diseases 1636

71-1 Cine loops of a two-dimensional echocardiogram from a patient with cardiac tamponade

71-2 Cine MR images in a patient with a pericardial effusion and underlying pulmonary hypertension

71-3 Cine MR images in a patient with both pericardial and pleural effusions

71-4 Cine MR images illustrating septal “bounce” in a patient with constrictive pericarditis

71-5 Cine MR images of a patient with constrictive pericarditis before pericardiectomy

71-6 Cine MR images of a patient with constrictive pericarditis after pericardiectomy illustrating relief of exaggerated ventricular interaction

REFERENCES, 19

Over the past decade, cardiovascular disease (CVD) has emerged as the single most important cause of death worldwide. In 2010, CVD caused an estimated 16 million deaths and led to 293 million disability-adjusted life-years (DALYs) lost¹—accounting for approximately 30% of all deaths and 11% of all DALYs lost that year. Like many high-income countries (HICs) during the past century, now low- and middle-income countries (LMICs) are seeing an alarming and accelerating increase in CVD rates.

This chapter describes the features of the epidemiologic transition underlying this shift in CVD morbidity and mortality and evaluates the transition in different regions of the world. Also presented is a survey of the current burden of risk factors and behaviors associated with CVD and their regional variations and trends, followed by a review of the economic impact of CVD and the cost-effectiveness of various strategies to reduce it. Concluding the chapter is a discussion of the diverse challenges posed by the increasing burden of CVD for various regions of the world, as well as potential solutions to this global problem.

SHIFTING BURDEN OF CARDIOVASCULAR DISEASE

CVD now causes the most deaths in all low- and middle-income regions, with the exception of sub-Saharan Africa, where it is the leading cause of death among persons older than 45 years of age. Between 1990 and 2010, deaths from CVD increased from 26% to 29.5% of all deaths globally—a reflection of the rapidity of the epidemiologic transition—particularly in low- and middle-income regions (**Fig. 1-1**). Within the six World Bank–defined low-income and middle-income regions, vast differences exist in the CVD burden (**Fig. 1-2**), with CVD death rates as high as 60% in Eastern Europe and as low as 10% in sub-Saharan Africa. The CVD death rate is 36% in HICs.

EPIDEMIOLOGIC TRANSITION IN PREDOMINANT CAUSES OF DEATH

Sequence of Stages

The overall increase in the global burden of CVD and the distinct regional patterns result in part from the epidemiologic transition, which includes four basic stages (**Table 1-1**)^{2,3}: pestilence and famine, receding pandemics, degenerative and manmade diseases, and delayed degenerative diseases. Progression through these stages has dramatically shifted the predominant causes of death over the past two centuries, from infectious diseases and malnutrition in the first stage to CVD and cancer in the third and fourth stages. Although the transition through the age of pestilence and famine has occurred much later in LMICs, it also has occurred more rapidly, driven largely by the transfer of low-cost agricultural technologies and public health advances.

Humans evolved during the age of **pestilence and famine** and have lived with these troubles for most of recorded history. Before 1900, infectious disease and malnutrition together constituted the most common cause of death in virtually every part of the world—with tuberculosis, pneumonia, and diarrheal diseases accounting for a majority of deaths. These conditions, along with high infant and child mortality rates, resulted in a mean life expectancy of approximately 30 years. Thanks largely to improved nutrition and public health measures, however, both communicable diseases and malnutrition declined, and life expectancy increased dramatically. Increased longevity and the impact of smoking, diets high in fat and carbohydrates, and other risk factors for chronic diseases, have now combined to make CVD and cancer the leading causes of death in most countries. This transformation in disease burden changes began in higher-income countries, but as they gradually have spread to LMICs, CVD mortality rates have increased globally. In absolute numbers, CVD causes four to five times as many deaths in LMICs as in HICs.

FIGURE 1-1 Changing patterns of mortality, 1990 to 2010. CMNN = communicable, maternal, neonatal, and nutritional diseases; CVD = cardiovascular disease; INJ = injury; ONC = other noncommunicable diseases. (From *Global Burden of Disease Study 2010. Global Burden of Disease Study 2010 mortality results 1970-2010*. Seattle, Institute for Health Metrics and Evaluation, 2012.)

Per capita income and life expectancy increase during the age of **receding pandemics** as the emergence of public health systems, cleaner water supplies, and improved food production and distribution combine to drive down deaths from infectious disease and malnutrition. These advances, in turn, increase the productivity of the average worker, further improving the economic situation with more urban migration as economies move from agrarian to industrially based economies. Improvements in medical education follow, and along with other public health changes, contribute to dramatic declines in infectious disease mortality rates. Rheumatic valvular disease, hypertension, and stroke cause most CVD. Coronary heart disease (CHD) often occurs at a lower prevalence rate than that for stroke, and CVD accounts for 10% to 35% of deaths.

During the stage of **degenerative and manmade diseases**, continued improvements in economic circumstances, combined with urbanization and radical changes in the nature of work-related activities, led to dramatic changes in diet, activity levels, and behaviors such as smoking. For example, in the United States, deaths from infectious diseases decreased to fewer than 50 per 100,000 people per year, and life expectancy was up to almost 70 years. The increased availability of foods high in saturated fat, coupled with decreased physical activity, leads to an increase in atherosclerosis. In this stage, CHD and stroke predominate, and between 35% and 65% of all deaths link to CVD. Typically, the ratio of CHD to stroke is 2:1 to 3:1.

In the age of **delayed degenerative diseases**, CVD and cancer remain the major causes of morbidity and mortality, but CVD age-adjusted mortality rates are nearly cut in half—accounting for 25% to 40% of all deaths. Two significant advances have contributed to the decline in CVD mortality rates: new therapeutic approaches, and prevention measures targeted at people with CVD and people at risk for it.⁴

Treatments once considered advanced—including the establishment of emergency medical systems and coronary care units and the

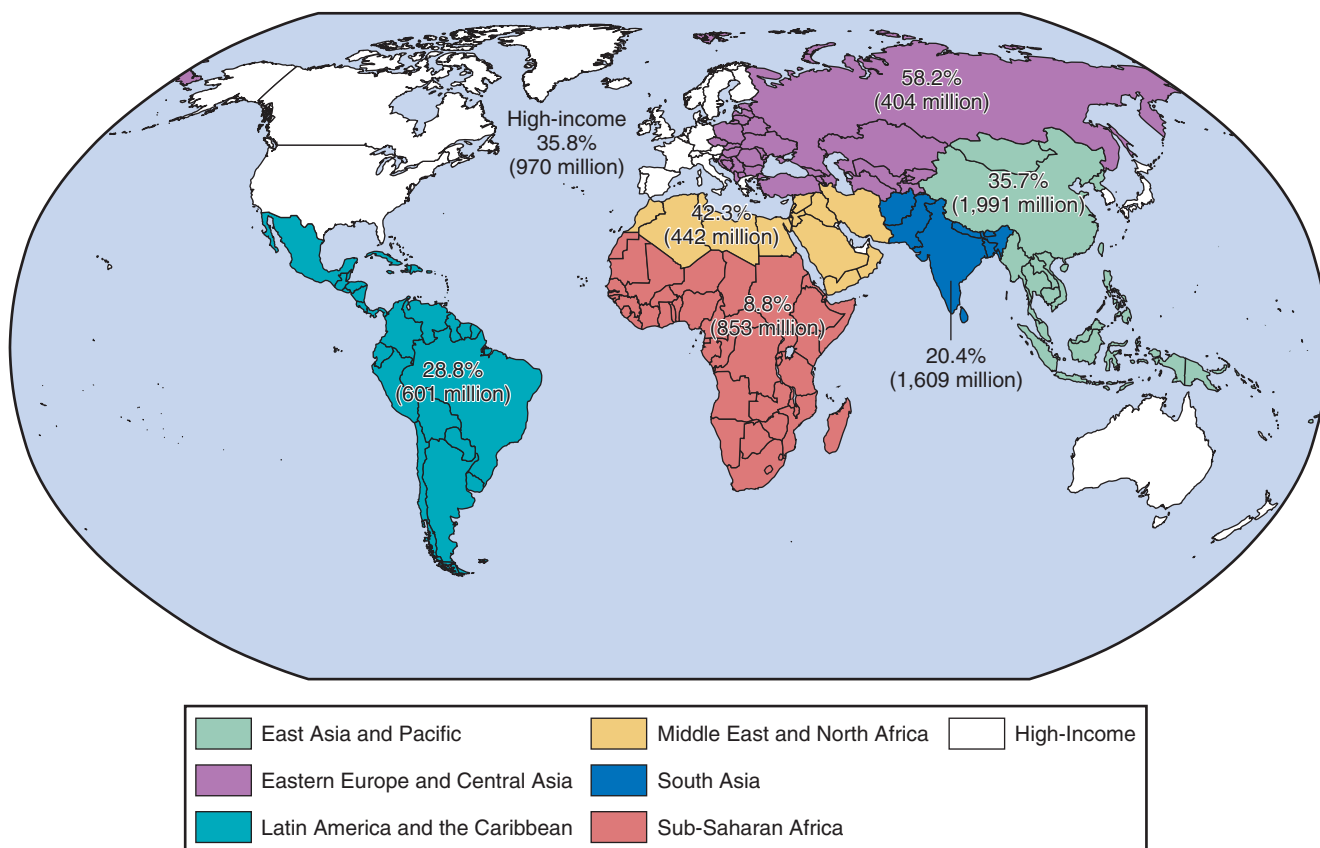

FIGURE 1-2 Cardiovascular disease deaths as a percentage of all deaths in each region and total regional population, 2010. (From *Global Burden of Disease Study 2010. Global Burden of Disease Study 2010 mortality results 1970-2010*. Seattle, Institute for Health Metrics and Evaluation, 2012.)

TABLE 1-1 Five Typical Stages of Epidemiologic Transition in Predominant Causes of Death

STAGE	DESCRIPTION	TYPICAL PROPORTION OF DEATHS CAUSED BY CVD (%)	PREDOMINANT TYPES OF CVD
Pestilence and famine	Predominance of malnutrition and infectious diseases as causes of death; high rates of infant and child mortality; low mean life expectancy	<10	Rheumatic heart disease, cardiomyopathies caused by infection and malnutrition
Receding pandemics	Improvements in nutrition and public health lead to decrease in rates of deaths caused by malnutrition and infection; precipitous decline in infant and child mortality rates	10-35	Rheumatic valvular disease, hypertension, CHD, stroke
Degenerative and manmade diseases	Increased fat and caloric intake and decreased physical activity lead to emergence of hypertension and atherosclerosis; with increased life expectancy, mortality rates for chronic, noncommunicable diseases exceed those for malnutrition and infectious diseases	35-65	CHD, stroke
Delayed degenerative diseases	CVDs and cancer are the major causes of morbidity and mortality; better treatment and prevention efforts help avoid deaths among those with disease and delay primary events Age-adjusted CVD mortality declines, with CVD affecting older and older individuals	40-50	CHD, stroke, congestive heart failure
Inactivity and obesity	Increasing obesity and diabetes prevalence rates; some decrease in CVD mortality rates in women	33	

CHD = coronary heart disease; CVD = cardiovascular disease.

Modified from Omran AR: *The epidemiologic transition: A theory of the epidemiology of population change*. *Milbank Mem Fund Q* 49: 509, 1981; and from Olshansky SJ, Ault AB: *The fourth stage of the epidemiologic transition: The age of delayed degenerative diseases*. *Milbank Q* 64:355, 1986.

widespread use of newer diagnostic and therapeutic technologies such as echocardiography, cardiac catheterization, angioplasty, bypass surgery, and implantation of pacemakers and defibrillators—have now become the standard of care. Advances in drug development also have had a major beneficial impact on both acute and chronic outcomes. Efforts to improve the acute management of myocardial infarction (MI) led to the application of lifesaving interventions such as beta-adrenergic blocking agent (beta blocker) therapy, percutaneous coronary intervention (PCI), use of thrombolytics, and angiotensin-converting enzyme (ACE) inhibitor therapy (see [Chapters 52 and 53](#)). The widespread use of an “old” drug, aspirin, also has reduced the risk of dying of acute or secondary coronary events. Low-cost pharmacologic treatment for hypertension (see [Chapter 44](#)), and the development of highly effective cholesterol-lowering drugs such as statins, also have made major contributions to both primary and secondary prevention by reducing CVD deaths (see [Chapter 45](#)).

In concert with these advances, public health campaigns have conveyed that certain behaviors increase the risk of CVD and that lifestyle modifications can reduce risk. In this regard, smoking cessation has been a model of success. In the United States, for example, 57% of men smoked cigarettes in 1955; today, 23% of men smoke. The prevalence of smoking among U.S. women has fallen, from 34% in 1965 to 18.5% today.⁵ Campaigns beginning in the 1970s resulted in dramatic improvements in the detection and treatment of hypertension in the United States. This intervention likely had an immediate and profound effect on stroke rates, and a more subtle effect on CHD rates. Public health messages concerning saturated fat and cholesterol had a similar impact on fat consumption and cholesterol levels. Between 1965 and 1995, overall U.S. fat consumption as a percentage of total calories fell from approximately 45% to 34%. Population mean cholesterol levels also declined, from 220 mg/dL in the early 1960s to 197 mg/dL by 2008,⁶ with a simultaneous decrease in the prevalence of elevated low-density lipoprotein (LDL) cholesterol.⁷

Is There a Fifth Phase: The Age of Inactivity and Obesity?

Troubling trends in certain risk behaviors and risk factors may foreshadow a new phase of the epidemiologic transition, the **age of inactivity and obesity**⁸ (see also [Chapter 42](#)). In many parts of

the industrialized world, physical activity continues to decline while total caloric intake increases at alarming rates, resulting in an epidemic of overweight and obesity. Consequently, rates of type 2 diabetes, hypertension, and lipid abnormalities associated with obesity are rising—trends that are particularly evident in children. These changes are occurring at a time when measurable improvements in other risk behaviors and risk factors, such as smoking, have slowed. If these trends continue, age-adjusted CVD mortality rates, which have declined over the past several decades in HICs, could level out as they have for young women in the United States,⁹ or even increase in the coming years. This trend pertains particularly to age-adjusted stroke death rates. Also concerning, even in LMICs, is the uptick in obesity. According to a recent study, one in five people in China are overweight or obese.¹⁰ Other new data indicate that as many as 40% of South African women may be overweight.

Fortunately, recent trends in the first decade of this century suggest there may be a tapering in the increases in obesity among adults, although the rates remain alarmingly high at nearly 34%.¹¹ Furthermore, continued progress in the development and application of therapeutic advances and other secular changes appear to have offset the effects from the changes in obesity and diabetes—cholesterol levels, for example, continue to decline. Overall, in this decade, the age-adjusted death rate has continued to decline at about 3% per year, from a rate of 341 per 100,000 population in 2000 to 245 per 100,000 in 2008.¹²

Different Patterns of Epidemiologic Transition

Given the large amount of economic, social, demographic, and health data available ([Table 1-2](#)), the United States serves as a useful reference point for other countries for a classical rise and decline of CVD mortality rates, with CHD rates as high as 600 per 100,000 population at their peak. Several HICs have proceeded through four stages of the epidemiologic transition and are perhaps entering the fifth phase, roughly in the same pattern as for the United States. But many HICs (i.e., Portugal, Spain, Italy, France, Greece, and Japan) never reached the high mortality rates observed in the United States and other countries, with CHD mortality rates of 200 per 100,000 or less. Nor did some countries have the same rapid rate of decline, with slower rates in central European countries (i.e., Austria, Belgium, and

**TABLE 1-2 Trends in the United States During the 20th Century**

Germany) compared with northern European countries (i.e., Finland, Sweden, Denmark, and Norway).¹³ Furthermore, reliable mortality data for the last 50 years are available for less than a fourth of all countries,¹³ with even less information for more than 50 years ago. In some countries, mortality rates appear to continue to rise (particularly, many that were part of the former Soviet Union), whereas others have yet to see any significant increase—such as many countries in sub-Saharan Africa (excluding South Africa). Whether LMICs will follow a “classical” pattern of significant increases followed by rapidly declining rates (as happened in North America, Australia, and northwestern European HICs), a more gradual rise and fall (as in the southern and central European countries), or some other pattern will depend in part on cultural differences, secular trends, and responses at the national level, with regard to both public health and treatment infrastructures.

CURRENT VARIATIONS IN THE GLOBAL BURDEN OF CARDIOVASCULAR DISEASE

Examination of regional trends is helpful in estimating global trends in the burden of disease, particularly CVD. Because 85% of the world’s population lives in LMICs, rates in these countries largely drive global CVD rates. Even as rates fall in HICs, CVD rates worldwide are accelerating, because most low- and middle-income regions are entering the second and third phases of the epidemiologic transition, marked by rising CVD rates.

Worldwide, the number of CVD deaths increased by 31% between 1990 and 2010, but age-adjusted death rates decreased by 21.2% in the same period, from 298 per 100,000 population to 235 per 100,000—suggesting significant delays in age at occurrence and/or improvements in case-fatality rates. DALYs lost as a result of CVD decreased as well,

from 4540 per 100,000 to 4282 per 100,000.¹⁴ Unfortunately, not all countries appear to share in the reductions. The magnitude of the peak of the CVD epidemic has a great range (Fig. 1-3; see also Figs. 1-1 and 1-2), with concomitant variability in whether the peak has been achieved at all. In this section, we describe and highlight trends in the seven regions of the world as defined by the Global Burden of Disease (GBD) project, which includes HICs as one grouping and divides the remaining LMICs into six geographic regions with a variety of subregions, outlined further on.

Our data for lives lost and DALYs come from the Global Burden of Diseases, Injuries, and Risk Factors Study 2010 (GBD 2010), which identified and compiled mortality data from 187 countries from 1980 to 2010.¹⁴ Although extensive, data from GBD 2010 have limitations. The availability and reliability of data on cause of death—especially in LMICs without standardized protocols—are uncertain. Data for demographic and social indices are from the World Bank’s World Development Indicators (WDI); those for gross national income (GNI) per capita are reported using the Atlas method in 2011 U.S. dollars.

In 2010, CHD accounted for 13.3% of all deaths worldwide. The second largest cause of death was stroke, at 11.1% (equally split between ischemic stroke and hemorrhagic and other nonischemic forms of stroke). An estimated 12.9 million people died from CHD and stroke, which together accounted for nearly a quarter of all deaths worldwide in 2010.¹⁴

Although still significant, deaths from communicable, neonatal, and maternal diseases are decreasing worldwide¹⁴—a 17% decrease occurred between 1990 and 2010. Deaths from noncommunicable diseases increased in the same time period. In 2010, CHD accounted for the largest portion of global years of life lost (YLLs) and DALYs. Stroke was the third-largest contributor to global YLLs and DALYs. By contrast, in 1990, communicable diseases accounted for the largest portion of both YLLs and DALYs.

LMICs have a high degree of heterogeneity with respect to the phase of the epidemiologic transition. First, LMIC subregions differ by age-adjusted CVD death rates, as well as by trends over the past 20 years (Fig. 1-4; see also Figs. 1-1 to 1-3). CVD mortality rates are increasing in most LMICs but are decreasing in HICs. Next, LMIC subregions are unique, as illustrated by the different CVD disease rates by cause in each region (Fig. 1-5). Finally, in the East Asia and Pacific and sub-Saharan regions, stroke still exceeds CHD as a cause of CVD death (Fig. 1-6). Countries in the East Asia and Pacific region appear to be following more of a Japanese-like transition, with relatively high stroke rates. Higher stroke rates in Africa, on the other hand, may reflect these countries' positions in an earlier stage of the epidemiologic transition. Hypertensive heart disease is the largest single contributor among remaining causes of CVD morbidity and mortality.

Variability in disease prevalence among various regions probably results from multiple factors. First, the countries are in various phases of the epidemiologic transition described earlier. Second, the regions may have cultural and/or genetic differences that lead to varying levels of CVD risk. For example, per capita consumption of dairy products (and thus consumption of saturated fat) is much higher in India than it is in China, although it is rising in both countries. Third, certain additional competing pressures exist in some regions, such as war or infectious diseases (human immunodeficiency virus infection/acquired immunodeficiency syndrome [HIV/AIDS]) in sub-Saharan Africa.

Because CHD afflicts a younger population in LMICs, an increased number of deaths affect the working population. For some LMICs, the severity of the epidemiologic transition has appeared to follow a reverse social gradient, with members of lower socioeconomic groups suffering the highest rates of CHD and the highest levels of various risk factors.¹⁵ Unfortunately, reductions in risk factors do not follow the same trend. Compared with people in the upper and middle socioeconomic strata, those in the lowest stratum are less likely to acquire and apply information on risk factors and behavior modifications, or to have access to advanced treatments. Consequently, CVD mortality rates decline later among those of lower socioeconomic status.

High-Income Countries

Demographic and Social Indices

Nearly 1 billion people (15% of the world's population) live in HICs, which are divided into four subregions: Asia-Pacific, Australasia, Western Europe, and North America. A majority of the population—close to 80%—is urban. Unlike other GBD regions, HICs are geographically dispersed but economically similar. The United States, the most populous of the HICs, has approximately 312 million people; Brunei Darussalam has the lowest population of 405,900 people.¹⁶ The highest life expectancies in the world occur in HICs, where the average life expectancy is 80 years.¹⁶ The GNI per capita in the region ranges from \$18,620 in Malta to \$88,890 in Norway. The United States is closer to the middle, with a GNI per capita of \$48,450. The region has high health expenditure, accounting for

FIGURE 1-3 Coronary heart disease mortality epidemic peaks and maxima in various countries in men 35 to 74 years of age (age-standardized). Symbols reflect exact location of data point. Two-letter country codes are as follows: AR = Argentina; AT = Austria; AU = Australia; AZ = Azerbaijan; BE = Belgium; BH = Bahrain; BR = Brazil; BU = Bulgaria; BY = Belarus; CA = Canada; CL = Chile; CU = Cuba; CZ = Czech Republic; DE = Germany; DK = Denmark; E&W = England and Wales; ES = Spain; FI = Finland; FR = France; GR = Greece; HK = Hong Kong; HU = Hungary; IE = Ireland; IL = Israel; IT = Italy; JP = Japan; KG = Kyrgyzstan; KW = Kuwait; NL = The Netherlands; NO = Norway; NZ = New Zealand; PL = Poland; PT = Portugal; RO = Romania; RU = Russian Federation; SC = Scotland; SE = Sweden; SG = Singapore; UA = Ukraine; UR = Uruguay; US = United States; UZ = Uzbekistan; VE = Venezuela. *Mortality did not reach a discernible peak by 2003. (From Mirzaei M, Truswell AS, Taylor R, Leeder SR: Coronary heart disease epidemics: not all the same. *Heart* 95:740, 2009.)

nearly a tenth of the region's gross domestic product (GDP). Brunei Darussalam and Singapore spend only 2.8% and 4.0% of their GDPs, respectively, on health care. The United States, on the other hand, spends nearly 18%, or \$8362 per capita. Other HICs—such as Norway, Luxembourg, and Switzerland—have similar per capita expenditures, although these account for much smaller portions of their GDPs.¹⁶

Burden of Disease

In 2010, CVD was responsible for 35.8% of all deaths in high-income regions, and CHD caused more than half of these deaths (see Fig. 1-6). The movement of most HICs through the epidemiologic transition, with rising levels of risk factors and CVD death rates until the 1970s and then declines in both over the next 40 years, resembles what occurred in the United States. CHD is the dominant form, with rates that tend to be twofold to fivefold higher than stroke rates. Two notable exceptions are Portugal, where stroke rates for both men and women are higher than CHD rates, and Japan, where stroke causes far more fatalities than CHD. In both of these countries, however, the pattern seems to be moving toward that seen in other HICs, with more rapid declines in stroke rates than in CHD rates.

Age-adjusted death rates for CVD declined in almost all high-income regions—with the exception of Asia-Pacific—between 1990 and 2010.¹⁴ This age-adjusted decline results largely from preventive interventions that allow people to avert disease, from treatments to prevent death during an acute manifestation of disease (particularly stroke or MI), and from interventions that prolong survival once CVD

FIGURE 1-4 Age-adjusted death rates per 100,000 for cardiovascular disease, 1990 and 2010. (From *Global Burden of Disease Study 2010. Global Burden of Disease Study 2010 mortality results 1970-2010*. Seattle, Institute for Health Metrics and Evaluation, 2012.)

is manifest. Thus, the average age at death from CVD continues to climb, and as a result, CVD affects a larger retired population.

Western Europe, with a CVD mortality rate of 367 per 100,000 in 2010, had the highest mortality rates, while Australasia had the lowest at 259 per 100,000. As mentioned above, mortality rates for CHD are higher than those for stroke in high-income regions, where CHD also accounts for a larger portion of all CVD deaths. The exception is Asia-Pacific, where death rates for stroke and CHD are 130 per 100,000 and 94 per 100,000, respectively. Mortality rates and number of deaths attributable to stroke and CHD increased in this region between 1990 and 2010; stroke rates increased by approximately 18%, whereas CHD rates increased by nearly 40%.¹⁴ Japan is unique among HICs—as its communicable disease rates fell in the early

20th century, its stroke rates increased dramatically. CHD rates, however, did not rise as sharply as they did in other industrialized nations, and have remained lower than in any other industrialized country. Overall, CVD rates have fallen 60% since the 1960s, largely because of a decrease in age-adjusted stroke rates. Japanese men and women currently have the highest life expectancies in the world: 86.4 years for women and 79.6 years for men. The difference between Japan and other industrialized countries may stem in part from genetic factors, but the Japanese fish- and plant-based, low-fat diet, and resultant low cholesterol levels, probably have played a more important role. Nevertheless, as is true for so many countries, dietary habits in Japan are undergoing substantial changes. Since the late 1950s, cholesterol levels have progressively increased in both urban and rural populations.¹⁷ Although the prevalence of CVD risk factors is increasing in the Japanese population, the incidence of coronary artery disease remains low. This situation could change, however, as there seems to be a long lag phase before dietary changes manifest as CHD events.

East Asia and Pacific Demographic and Social Indices

The EAP region is the most populated low-income and middle-income region in the world, with nearly 2 billion people; approximately 49% of the region is urban. The GNI per capita is \$4243, ranging from \$4420 in Thailand to \$1130 in Laos. In 2004, total health expenditure was 4.8% of total GDP, or \$183 per capita.¹⁶ The region is divided into three distinct subregions: Southeast Asia, East Asia, and Oceania. China is by far the most populated country, representing almost 70% of the region. Life expectancy has risen quickly across the EAP region in past decades, up to an average of 72 years. In China, the increase has been dramatic: from 37 years in the mid-1950s to 73 years in 2010.¹⁶ This increase has been accompanied by a large rural to urban migration pattern, rapid urban modernization, aging of the population, decreased birth rates, major dietary changes, increasing tobacco use, and a transition to work requiring low levels of physical activity.

Burden of Disease

CVD caused more than 4.5 million deaths in the EAP region in 2010, accounting for 35.2% of all deaths in the region. More than half of those deaths resulted from ischemic heart disease, whereas only 31% were due to stroke

(see Fig. 1-6). CVD death rates differed significantly between subregions, most notably in Oceania. Mortality rates were highest in East Asia, at 234 per 100,000 in 2010. Death rates in Oceania, on the other hand, were 110 per 100,000, well below the global average. Between 1990 and 2010, death rates for CVD increased in all three subregions, although to various degrees. Rates in East Asia and Southeast Asia increased by approximately 24%, but by only 3% in Oceania. In Southeast Asia and East Asia, CVD accounts for the largest percentage of total DALYs lost in the regions (26 million and 67 million, respectively).¹⁴

Stroke and CHD are the leading causes of death in the East Asia and Southeast Asia subregions. In Oceania, however, lower respiratory infections and diabetes account for the largest proportion of

deaths. Whereas stroke and CHD rates increased in both East Asia and Southeast Asia, stroke rates decreased slightly in Oceania, from 40 per 100,000 to 36 per 100,000.¹⁴ China appears to be straddling the second and third stages of a Japanese-like epidemiologic transition. Among men in China 35 to 64 years of age, stroke death rates are 217 to 243 per 100,000, versus CHD death rates of 64 to 106 per 100,000.¹⁸

Even with high stroke rates, CHD is emerging as a large and growing burden in East Asia. Data from the largest death registration and classification study in China showed that CHD accounted for 13% to 22% of overall CVD deaths and 4% to 9% of total deaths, with the higher percentages seen in urban areas.¹⁹ In 2004, the World Health Organization (WHO) estimated that nearly 400,000 people in China died from CHD, and that 652,000 cases of CHD were diagnosed.¹⁹ The rates for age-adjusted mortality from CHD were 80 to 128 per 100,000 for men and 57 to 98 per 100,000 for women.¹⁹ Higher rates were seen in urban areas than in rural areas (by a factor of six), in higher-income areas than in lower-income areas, and in northeastern areas of China than in southern areas.¹⁹

CHD rates have grown quickly over the past two decades in China. Age-adjusted CHD mortality increased 39% in women and 41% in men, 35 to 74 years of age, between 1984 and 1999. Furthermore, the incidence of CHD increased by 2.7% annually in men and 1.2% annually in women. Although rates are higher, hospitalizations are somewhat low. Acute MI was the diagnosis in 4.1% of all hospital discharges in 2004 in large cities, and in 2.1% of discharges in smaller cities and rural areas.¹⁹

Central and Eastern Europe and Central Asia

Demographic and Social Indices

Of the three subregions that constitute this region—Central Asia, Central Europe, and Eastern Europe—Eastern Europe is the most populated. Russia alone accounts for more than 30% of the region's 404 million inhabitants. Sixty-five percent of the population in the region is urban, with an average life expectancy of 71 years. The average GNI per capita for the region ranges from \$870 in Tajikistan to \$23,610 in Slovenia. Russia has a GNI of \$10,400. On average, the region spends more than 6% of total GDP on public and private health care. Health expenditure per capita ranges from \$49 per capita in Tajikistan to \$2154 in Hungary. Russia spends about \$525 per capita, or 5.1% of its GDP.¹⁶

Burden of Disease

The highest rates of CVD mortality occur in this region. CVD mortality rates are 866 per 100,000 in Eastern Europe and 604 per 100,000 in Central Europe. Overall rates resemble those seen in the United States in the 1960s, when CVD was at its peak. CHD is generally more common than stroke, which suggests that the countries that constitute Eastern Europe and Central Asia are largely in the third phase of the epidemiologic transition. As expected in this phase, the average age of people who develop and die of CVD is lower than that in high-income economies. In 2010, CVD accounted for nearly two thirds of all deaths in the region, 58.3% of which were due to CHD and 33.5% due to stroke. In Eastern Europe alone, 29.7 million DALYs were lost as a result of CHD in 2010.¹⁴

A country-level analysis reveals important differences in CHD profiles within the region (see Fig. 1-3). Since the dissolution of the Soviet Union, CVD rates have increased surprisingly in some of these countries, with the highest rates (nearly 800 per 100,000 for men) in Ukraine, Bulgaria, Belarus, and Russia.¹³ In Russia, increased CVD

FIGURE 1-5 Cardiovascular disease death by specific cause and region, 2010. CHD = coronary heart disease; HHD = hypertensive heart disease; RHD = rheumatic heart disease. (From *Global Burden of Disease Study 2010. Global Burden of Disease Study 2010 mortality results 1970-2010*. Seattle, Institute for Health Metrics and Evaluation, 2012.)

rates have contributed to falling life expectancy—particularly for men, whose life expectancy dropped steadily from 71.6 years in 1986 to as low as 58 years in 1999. Yet, life expectancy has trended upward in more recent years—67.6 years for men in 2010—even as CVD mortality rates have increased.

FIGURE 1-6 Comparison of percentages of cardiovascular disease mortality attributable to coronary heart disease (CHD) and stroke by region, 2010. EAP = East Asia and Pacific; ECA = Eastern and Central Europe and Central Asia; LAM = Latin America and the Caribbean; MEN = Middle East and North Africa; SAR = South Asia region; SSA = sub-Saharan Africa. (From *Global Burden of Disease Study 2010. Global Burden of Disease Study 2010 mortality results 1970-2010.* Seattle, Institute for Health Metrics and Evaluation, 2012.)

By 2010, CVD mortality rates in the region were the highest in the world. Importantly, deaths resulting from CHD in these countries are not restricted to older adults. The GBD study estimates that working-age populations (15 to 69 years of age) have a significant CHD burden. Nearly a third of all deaths in persons 45 to 49 years of age, for example, result from CVD. For people 60 to 64 years of age, CVD accounts for half of all deaths, 27% of which are due to CHD.¹⁴

Latin America and the Caribbean

Demographic and Social Indices

The Latin America and Caribbean (LAM) region comprises Andean Latin America, Central Latin America, Southern Latin America, Tropical Latin America, and the Caribbean. The region has a total population of 589 million, 79% of which is urban.¹⁶ Brazil, the region's most populous country, represents a third of the population, with Argentina, Colombia, Mexico, Peru, and Venezuela making up another third. The Caribbean nations, including the Dominican Republic, Jamaica, and Haiti, account for less than 10% of the population in the region. Life expectancy in the region is approximately 74 years but varies greatly. In 2010, for example, Haiti and Cuba had life expectancies of 64 years and 79 years, respectively. Average GNI per capita in the region is around \$8544 (purchasing power parity [PPP] of \$11,587). The region spends an average of 7.7% of its GDP on health care. This level of spending translates into health care expenditures that range from \$46 per capita in Haiti to \$1003 per capita in Barbados.¹⁶

Burden of Disease

This area bears a substantial CVD burden. In 2010, CVD caused 28.8% of all deaths in the region.¹⁴ Unlike in HICs, where CHD dominates among circulatory diseases, CHD and cerebrovascular disease contribute similarly to mortality in this region (see Fig. 1-6), pointing to relatively higher rates of untreated hypertension.

Mortality rates vary significantly by subregion (see Fig. 1-3). Mortality rates for CHD and stroke are highest in the Caribbean (100 deaths per 100,000 population and 125 per 100,000, respectively); unlike global trends, both mortality rates increased between 1990 and

2010. Death rates also increased in Central Latin America and Andean Latin America; similar increases in mortality rates occurred in Tropical Latin America. Together, CHD (14%), stroke (6.9%), and hypertensive heart disease (2.1%) accounted for nearly a quarter of all deaths in Central Latin America in 2010. Southern Latin America—which includes Argentina, Chile, and Uruguay—was the only subregion to follow global patterns in mortality rates. Overall CVD, CHD, and stroke mortality rates decreased in this subregion between 1990 and 2010, but to a lesser extent than for global changes.¹⁴ The lower reductions in the region are attributed to rapid lifestyle changes—unfavorable dietary changes, increased smoking, increased obesity, and less exercise.

North Africa and the Middle East

Demographic and Social Indices

The 19 countries of the North Africa and Middle East region represent approximately 5% of the world's population (337 million people). Egypt and Iran are the two most populous countries in the region, with Egypt representing 24% of total inhabitants and Iran 22%. Approximately 59% of the population is urban, with an average life expectancy of 72 years. The average GNI per capita for the region is \$3869, ranging from \$1070 in Yemen to \$48,900 in Kuwait. Approximately 5.3% of the GDP, or approximately \$203 per capita, is used for health expenditures in the region. The per capita health expenditure ranges from \$63 in Yemen to \$1450 in the United Arab Emirates.¹⁶

Burden of Disease

Forty-two percent of all deaths in the region are attributable to CVD, 47% of which are due to CHD and 30% are due to stroke. CVD mortality rates for the region are lower than global averages. In 2010, the death rate per 100,000 for CHD, stroke, and overall CVD were 93, 59, and 199, respectively. Unlike global trends, the mortality rate for CHD increased in the region by approximately 15%. Neither stroke nor CVD mortality rates decreased significantly. In 2010, CVD accounted for 17.2 million DALYs, 14% of all DALYs lost in the region. The DALYs lost were split evenly between CHD and stroke, at 6.8 million and 5.0 million, respectively.¹⁴

Individual country data show that 12 of the region's countries rank in the top 50 in age-adjusted CHD mortality rates. Somalia, Iraq, and the Sudan are in the top 25 with rates of 219, 214, and 212 per 100,000, respectively.²⁰ Iran may have a higher prevalence burden than other countries, including Saudi Arabia and Jordan. A study of a random sample of 3723 people in Iran found that 11.3% had coronary symptoms, and an additional 1.4% had an MI; the age-adjusted prevalence was therefore 12.7%.²¹ In Jordan, a study showed that 5.9% of 3083 participants had an MI.²²

South Asia

Demographic and Social Indices

The South Asia region (SAR), one of the world's most densely populated regions, comprises about 24% of the world's population with more than 1.6 billion residents. India, home to nearly 75% of the region's inhabitants, is the largest country in the region. Only 31% of the region is urban, and life expectancy is approximately 65 years.

Average GNI per capita for the region is \$1299, ranging from \$540 in Nepal to \$6530 in Maldives. India's GNI per capita of \$1410 sits near the regional average. Countries in the SAR spend an average of 3.9% of the total GDP, or \$47 per capita, on health care. Maldives spends the most per capita at \$208, and India spends \$31, or 5% of its GDP. The lowest expenditures for health care are \$22 per capita in Pakistan and \$23 in Bangladesh.¹⁶

Burden of Disease

CVD accounts for 20% of all deaths in the SAR. CHD was the leading cause of mortality in 2010—responsible for 10.6% of total reported fatalities, or 1.8 million deaths, and more than half of CVD mortality. Cerebrovascular disease accounted for 6.8% of all deaths and 30% of CVD deaths. Nearly 60.5 million DALYs are lost due to CVD in the region, accounting for 10% of all DALYs lost. CHD is responsible for 4.6% of the DALYs lost because of CVD, nearly twice as high as for stroke.¹⁴ Mortality rates for CVD are increasing in the region.

Several studies in India and Pakistan suggest substantial morbidity and mortality resulting from CHD in this region. In 1990, 1.18 million people died in India as a consequence of CHD; by 2010, this number increased to an estimated 2.03 million.²³ CVD probably represents 25% of all deaths in India. Studies also show that CHD prevalence is higher in men and in urban residents.²³ Prevalence of CHD in India recently was estimated at more than 10% in urban areas and 4.5% in rural areas.²³ A recent CHD study in Pakistan found a prevalence of approximately 6% in men and 4% in women, but active ischemia was twice as frequent in women. The study authors suggest that one in five adults in urban parts of Pakistan have CHD,²⁴ and that only a fourth of these adults are aware of their disease and seeking medical care. In contrast with the epidemiologic transition in HICs, recent evidence suggests that residents of the SAR of lower socioeconomic status are developing a higher burden of CHD first.²⁵ Tobacco use and hypertension, for example, were both significantly more prevalent among cohorts with lower levels of education.²⁵

Another demographic trend in the SAR is a considerable increase in urban residents, a shift that usually correlates with increased rates of CHD. Currently, 31% of all inhabitants in the region live in an urban setting, a number that is expected to rise.¹⁶ A review of epidemiologic studies in the country found that between 1965 and 2005, CHD prevalence increased from approximately 4% to 12% in urban populations.²³ Rural populations are experiencing similar increases in CHD prevalence. More recent data from the rural region of Andhra Pradesh in South India suggest an actually higher prevalence in many rural regions.²⁶ CHD death rates exceeded 15% in this study, meaning that the rural-versus-urban protection factor no longer exists—or that the urban rates, if measured more carefully, could be much higher.

The rise in CHD mortality contributes to the economic burden in the Indian subcontinent. Data indicate that symptoms of CHD arise a full 5 to 10 years earlier in this region than in Western European and Latin American countries.²⁷ Furthermore, CVD affects a substantial proportion of working-age citizens. A study in rural India, for example, found that 51% of all CVD deaths occurred in individuals younger than 70 years of age.²⁶

Sub-Saharan Africa Demographic and Social Indices

The GBD study divides sub-Saharan Africa into four subregions: Central Africa, East Africa, Southern Africa, and Western Africa. Approximately 875 million people live in these four regions, with Nigeria being the most populous (163 million) and Cape Verde being the least populous (500,600). Only 36% of the population in the region is urban. The average GNI per capita is \$1255, ranging from \$250 in Burundi to \$7480 in Botswana. Overall, the region also has the lowest average life expectancy—54 years.¹⁶

Average public and private health care expenditures for the region are 6.5% of the total GDP, or \$84 per capita. The range of health care expenditures per capita for the region is similar to the GDP range for this region, from \$3 in Burundi to \$511 in Seychelles. Nigeria spends \$23 per capita, or 4.6% of the total GDP.²⁸

Burden of Disease

In Western Africa, CVD accounts for 7.5% of all deaths. The highest portion of CVD-caused deaths occurred in Southern Africa, where 13% of all deaths were due to CVD. Mortality rates in the region are lower than global averages, and are decreasing, in line with global trends. The exception is Southern Africa, where rates increased from 129 per 100,000 to 136 per 100,000. Communicable, neonatal, and maternal disorders still dominate causes of death in the sub-Saharan region. Malaria and HIV/AIDS are the leading causes of death, accounting for nearly half of all deaths in the region.¹⁴

Human Immunodeficiency Virus Infection and Coronary Heart Disease

In view of the large burden of disease attributable to HIV/AIDS, the potential risk of CVD among persons being treated with antiretroviral medications is of growing concern (see Chapter 70). As in HICs, CVD death appears to be rising among people older than 65 years of age in rural South Africa.²⁹ For those between 50 and 64 years of age, however, CVD deaths appear to have halved in South Africa, probably as a consequence of competing HIV/AIDS mortality.²⁹ HIV-seropositive men older than 50 years of age have a higher prevalence of dyslipidemia, diabetes, and peripheral artery disease (50% of cases were asymptomatic), compared with their noninfected counterparts.³⁰ Of note, 55% of these HIV-infected men were prior smokers, and they also were more likely to use antihypertensive drugs, lipid-lowering agents, and antidiabetic medications. A recent study of 95 patients initiating antiretroviral drugs indicated that patients who had high baseline lipid levels showed a marked increase in lipoprotein(a).³¹ The coupling of HIV infection with expanding uptake of antiretroviral therapy (ART), particularly in South and East Africa,³²⁻³⁴ adds another layer of complexity. Today, HIV/AIDS can be regarded as a treatable chronic illness, with the expectation that persons with HIV/AIDS will live longer and lead more active lives, consequently increasing their noncommunicable disease risk.³⁵ HIV infection appears to have an independent cardiovascular effect, and treatment with ART may cause dyslipidemia.^{36,37} Further studies suggest that in addition to these mechanisms, HIV seropositive status may serve as a marker to identify a subgroup of persons at high risk for development of CVD.³⁸ Collectively, these data indicate that the interaction of seropositive HIV status, ART, and risk for acquiring CVD warrants continued attention.

RISK FACTORS

CVD worldwide is largely driven by modifiable risk factors, such as smoking, lack of physical activity, and diets high in fat and salt (see also Chapters 42 to 45 and 61). The INTERHEART study showed that smoking, hypertension, abdominal obesity, physical inactivity, and a high-risk diet were responsible for a significant component of MI risk.³⁹ Elevated levels of blood pressure (BP) and cholesterol remain the leading causes of CHD; tobacco, obesity, and physical inactivity remain important contributors as well.

The GBD project estimated that the population-attributable fraction (PAF) for individual risk factors for CHD in LMICs in 2001 were as follows: high BP, 44%; high cholesterol, 46%; overweight and obesity, 16%; low fruit and vegetable intake, 30%; physical inactivity, 21%; and smoking, 15%. Unique features regarding some CHD risk factors in LMICs are described next.

Tobacco

By many accounts, tobacco use is the most preventable cause of death in the world. Over 1.3 billion people use tobacco worldwide, more than 1 billion of whom smoke⁴⁰; the rest use oral or nasal tobacco. More than 80% of tobacco use occurs in LMICs, and if current trends continue unabated, tobacco will cause more than 1 billion deaths during the 21st century (Fig. 1-7).

Tobacco use varies greatly across the world (see Fig. 1-7). Although historically greatest in HICs, tobacco consumption has shifted

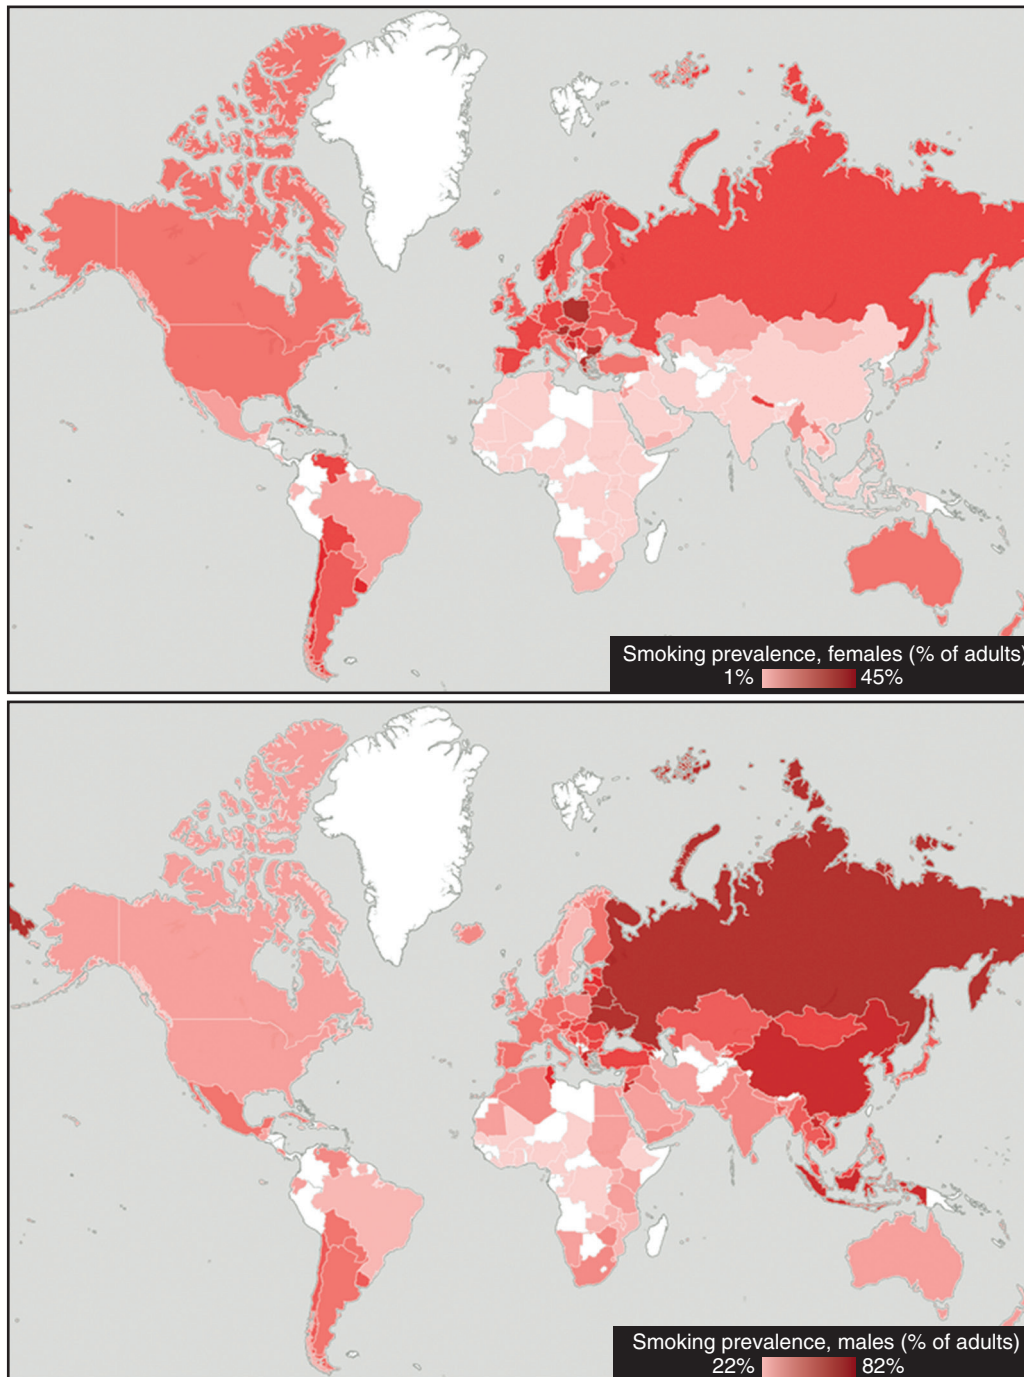

FIGURE 1-7 Smoking prevalence among persons 15 years of age or older, females (top) and males (bottom), for 2008 to 2012. (From World Bank. *World Development Indicators*, 2010 [<http://data.worldbank.org/indicator>].)

dramatically to LMICs in recent decades; some of the highest tobacco use now occurs in the EAP region. Kiribati has the highest prevalence of age-adjusted tobacco use in the world—71.0% in men and 42.9% in women. Indonesia has similarly high rates (>60% prevalence in men). China is the largest consumer of tobacco in the world, with an estimated 301 million smokers in 2010 (>50% prevalence in men). Several countries in the Central and Eastern Europe regions also have alarmingly high prevalence rates, including Russia (approximately 60.0% in men and 24.3% in women), Ukraine (>50% prevalence in men), and Albania (60% prevalence in men). Latin America, the Middle East, and North Africa have high rates as well, although smoking is not as common among women in these regions as it is in the Pacific region. Countries in sub-Saharan Africa have some

of the lowest prevalence rates; Niger and Ethiopia, for example, have less than 10% and 1% prevalence in men and women, respectively.

High rates of smoking are not limited to men. Smoking prevalence among women is high—and increasing—in several countries in the world, including Kiribati (42.9%), Austria (45.1%), Nauru (50%), and Greece (41.4%). In general, however, considerably more men than women smoke. Exceptions to this pattern include Nauru and Greece, which have comparable tobacco use prevalence in men and in women. Where they do occur, variations by sex can be substantial. In China, for example, tobacco use prevalence is 50% in men but only 2.2% in women. Indonesia has similarly diverging trends: prevalence in men is 61.3%, and only 5.1% in women. Significant variations

also occur in North Africa, the Middle East, and some countries in sub-Saharan Africa. Tobacco use is generally less than 1% in women in these regions, but is much higher in men.

Other forms of tobacco use increase risk for CHD. Bidis (hand-rolled cigarettes common in South Asia), kreteks (clove and tobacco cigarettes), hookah pipes (water pipes used for smoking flavored tobacco), and smokeless tobacco all link to increased CHD risk.^{41,42} The combined use of different forms of tobacco is associated with a higher risk of MI than using one type.

Secondhand smoke is another well-established cause of CHD. In 2011, approximately 600,000 nonsmokers died as a consequence of exposure to secondhand smoke. A retrospective analysis of 192 countries found that the largest portion of secondhand smoke-related deaths in 2004 resulted from ischemic heart disease.⁴³ These observations may explain the large and immediate drop seen in communities such as Helena, Montana, and in Scotland, which implemented smoke-free laws and found 20% to 40% decreases in admissions for MI, controlling for time, locality, and other variables.⁴⁴ Smoking bans have both immediate and long-term effects in reducing admissions for acute coronary syndrome (ACS). In Ireland, which implemented a country-wide smoking ban in workplaces, ACS-related hospital admissions promptly decreased by 12%, and 2 years after the implementation of the ban such admissions decreased by an additional 13%.⁴⁵

Hypertension

Elevated BP is an early indicator of epidemiologic transition. Rising mean population BP occurs as populations industrialize and move from rural to urban settings. Worldwide, approximately 62% of strokes and 49% of CHD cases are attributable to suboptimal (above 115 mm Hg systolic) BP, a factor thought to account for more than 7 million deaths annually. A relatively recent study by Lawes and co-workers estimated that 14% of deaths and 6% of DALYs lost globally were due to nonoptimal levels of BP.⁴⁶ Although most societies define hypertension as a systolic BP greater than 140 mm Hg, Lawes and colleagues found that just over half of the attributable CVD burden occurs among persons with a systolic BP less than 145 mm Hg. The high rate of undetected, and therefore untreated, hypertension presents a major concern in LMICs. The high prevalence of undetected and untreated hypertension probably drives the elevated rates of hemorrhagic stroke throughout Asia.

The most recent update of the GBD study analyzed mean systolic BP between 1980 and 2008 using multiple published and unpublished health surveys and epidemiologic studies. The analysis—which applied a Bayesian hierarchical model to each sex by age, country, and year—found a global decrease in mean systolic BP between 1980 and 2008 in both men and women.⁴⁷ Worldwide, the age-standardized prevalence of uncontrolled hypertension has decreased from 33% to 29% in men, and from 29% to 25% in women, between 1980 and 2008. But the number of people with uncontrolled hypertension (systolic BP of 140 mm Hg or higher) has increased—in 1980, 605 million had uncontrolled hypertension, and by 2008, the number increased to 978 million. The trend results largely from population growth and aging. Globally, mean systolic BP has decreased by 0.8 mm Hg per decade among men; the number is slightly higher among women, at 1.0 mm Hg per decade. In 2008, age-standardized mean systolic BP values worldwide were 128.1 mm Hg in men and 124.4 mm Hg in women.

Regional and sex variations exist in systolic BP (Fig. 1-8). The highest mean systolic BP in 2008 occurred in East and West African countries, where both men and women had systolic BP levels that were significantly higher than global averages. In Mozambique and São Tomé and Príncipe, for example, mean systolic BP in women was 135.4 mm Hg and 136.3 mm Hg, respectively. In men, mean systolic BP was as high as 137.5 mm Hg in Mozambique and 139.4 mm Hg in Niger. Men in Eastern Europe had mean systolic BP levels comparable to those in East and West Africa. Mean systolic BP was lowest in high-income regions such as Australasia (systolic BP of 117.4 mm Hg in Australian women) and North America (systolic BP of 123.3 mm Hg in U.S. men).

The most significant decreases occurred in high-income regions, where mean systolic BP decreased by 2.4 mm Hg per decade in men and 3.1 mm Hg per decade in women. The decrease in men ranged from 1.7 mm to 2.8 mm Hg per decade, with the greatest decrease occurring in the North America subregion. The decrease in mean systolic BP in women ranged from 2.3 mm Hg per decade in North America to 3.9 mm Hg per decade in Australasia.

Mean systolic BP increased in several regions. In South Asia, systolic BP increased by 0.8 mm Hg per decade in men and 1.0 mm Hg per decade in women. Southeast Asia saw similar increases: 0.9 mm Hg per decade in men and 1.3 mm Hg per decade in women. In East Africa, mean systolic BP increased by 1.6 mm Hg per decade in men and 2.5 mm Hg per decade in women. The most significant increases in men occurred in East Africa (1.6 mm Hg per decade). In women, mean systolic BP increased the most in Oceania (2.7 mm Hg per decade).

Notable sex differences occurred in Oceania and West Africa. In Oceania, mean systolic BP increased by 2.7 mm Hg per decade, the largest increase in any female cohort in the world. In men in this region, on the other hand, mean systolic BP increased by only 1.2 mm Hg per decade. Data from West Africa show diverging trends in mean systolic BP in men and women. Although mean systolic BP decreased in men in West Africa by 0.4 mm Hg per decade, systolic BP in women in this subregion increased by 2.5 mm Hg per decade.

Lipids

Worldwide, high cholesterol causes some 56% of ischemic heart disease and 18% of strokes amounting to 4.4 million deaths annually. Unfortunately, most LMICs have limited data on cholesterol levels, and often only total cholesterol values are collected. In HICs, mean population cholesterol levels are generally decreasing, but in LMICs, these levels vary widely. As countries move through the epidemiologic transition, mean population plasma cholesterol levels typically rise. Changes accompanying urbanization clearly play a role, as plasma cholesterol levels tend to be higher among urban residents than among rural residents. This shift results largely from greater consumption of dietary fats—primarily from animal products and processed vegetable oils—and decreased physical activity.

Globally, mean serum total cholesterol levels have decreased.⁴⁸ The GBD study analyzed data between 1980 and 2008 using a Bayesian model to estimate mean total cholesterol by age, country, and year. Age-standardized mean total cholesterol was 4.64 mmol/L (179.6 mg/dL) in men and 4.76 mmol/L in women in 2008 (184.2 mg/dL). Some of the highest levels of cholesterol occurred in high-income regions (Fig. 1-9). In 2008, the combined regions of Australasia, North America, and Western Europe had a mean total cholesterol of 5.24 mmol/L in men and 5.23 mmol/L in women. In Greenland, mean total cholesterol was as high as 5.7 mmol/L for both sexes. Sub-Saharan Africa had the lowest levels for both sexes. Some cohorts—largely, men in Southern African countries like Liberia, Nigeria, and Burkina Faso—had levels less than 4.0 mmol/L.

Between 1980 and 2008, mean total cholesterol levels decreased by 0.08 mmol/L per decade in men and by 0.07 mmol/L per decade in women. The most significant decreases in cholesterol levels occurred in the Central Europe, Eastern Europe, and Central Asia regions: 0.23 mmol/L per decade in men, and 0.24 mmol/L per decade in women. The high-income regions of Australasia, North America, and Western Europe had similarly large decreases in cholesterol levels: 0.19 mmol/L per decade in men, and 0.21 mmol/L per decade in women. Countries like Finland and Sweden had notably faster decreases in cholesterol levels than other Western European countries.

Several exceptions to the worldwide downward trend in cholesterol levels occurred. In the EAP region, levels increased by 0.08 mmol/L per decade in men and by 0.09 mmol/L per decade in women. The high-income Asia-Pacific subregion showed a similar trend, but the increase was more moderate (≤ 0.1 mmol/L per decade). South Korea demonstrated no change in cholesterol levels as a result of maintaining a diet low in saturated fats. Singapore data were also

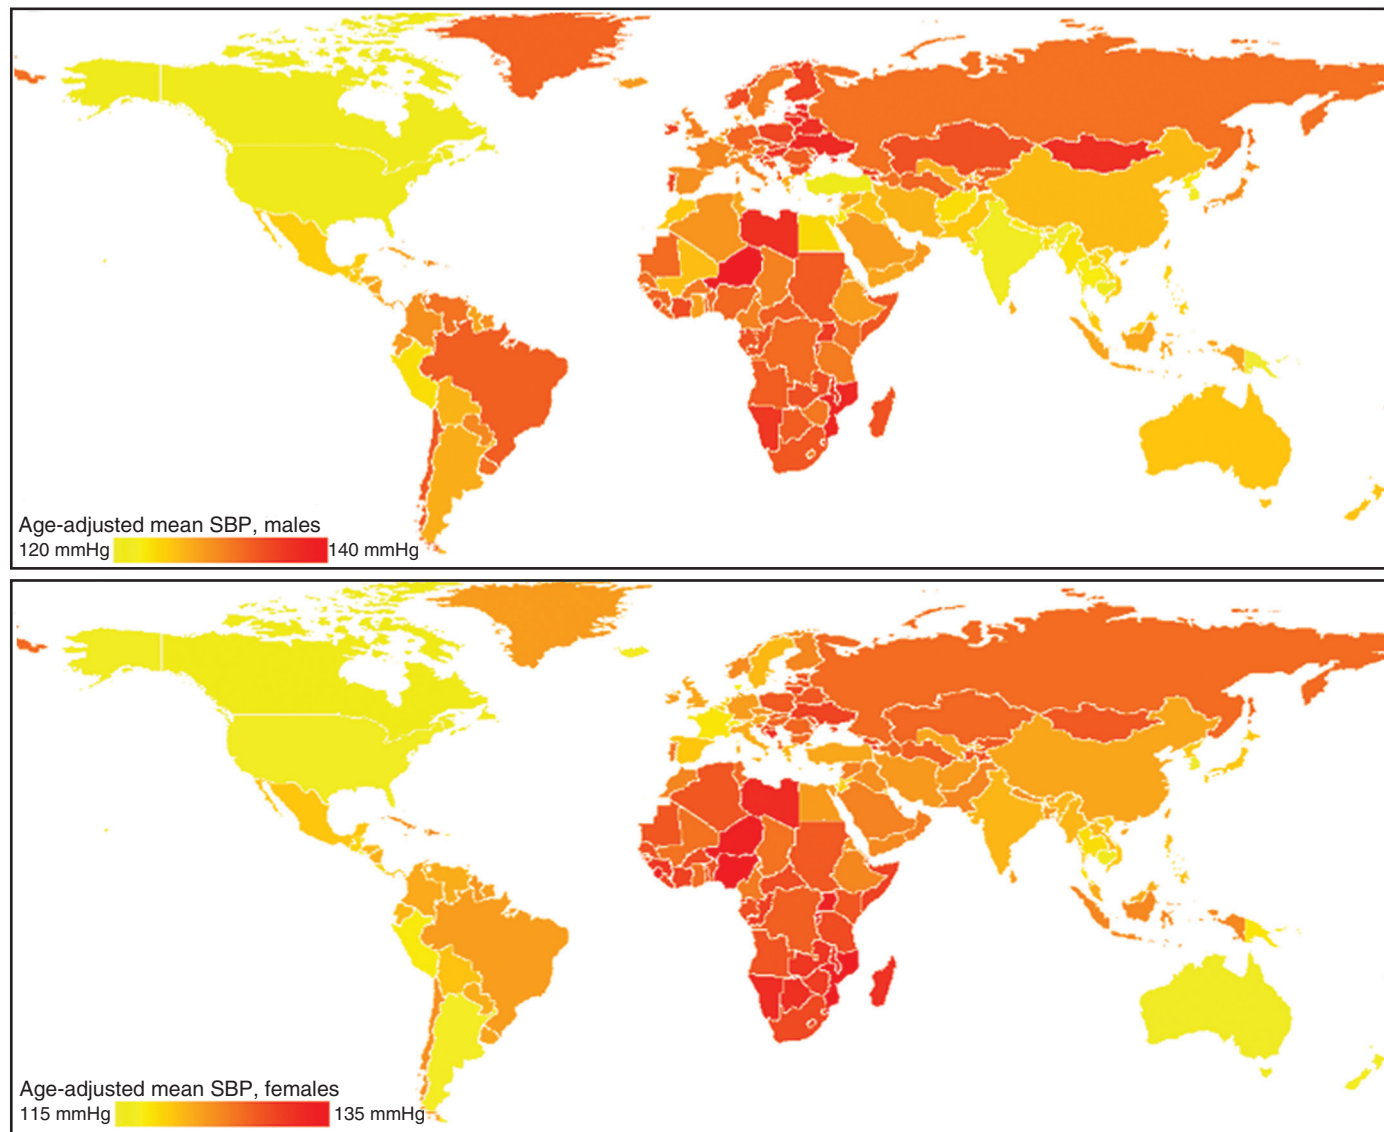

FIGURE 1-8 Age-adjusted mean systolic blood pressure (SBP) for males (top) and females (bottom), 2008. (From Goodarz D, Finucane MM, Lin JK, et al: National, regional, and global trends in serum total cholesterol since 1980: Systemic analysis of health examination surveys and epidemiological studies with 786 country-years and 5.4 million participants. *Lancet* 377:568, 2011.)

notable: In the 1980s, cholesterol levels decreased for both men and women, but beginning in 2000, the downward trend ended in men. In women, the trend reversed, increasing from 4.7 mmol/L in 2000 to 5.3 mmol/L in 2008. Several regions—including North Africa and Middle East, sub-Saharan Africa, and South Asia—showed no notable change in cholesterol levels, owing in part to a lack of available historical data. In general, women in low-income and middle-income subregions had higher total cholesterol than their counterparts in HICs.

Diabetes

The incidence of diabetes has grown rapidly worldwide in the past 30 years. According to the GBD study, an estimated 346 million people worldwide have diabetes.⁴⁹ The more expansive International Diabetes Foundation (IDF) Atlas definition—which, in addition to fasting plasma glucose (FPG) as in the GBD study, includes oral glucose tolerance and HbA_{1c} tests—found that 366 million people had diabetes in 2011. Nearly 50% of these cases were undiagnosed. By 2030, the number of people with diabetes is expected to increase to 522 million. This increase is estimated to occur at 2.7% annually, a higher growth rate than that of the total world adult population.

Eighty percent of people with diabetes live in LMICs (**Fig. 1-10**). The highest regional prevalence for diabetes occurs in the Middle East and North Africa, where an estimated 12.5% of the adult population (20 to 79 years of age) has diabetes. Pacific island and Middle Eastern countries have the highest prevalence, with age-adjusted prevalence ranging from 18.8% to 25.4%. Future growth will be concentrated in LMICs, especially in regions such as sub-Saharan Africa, Middle East and North Africa, and Southeast Asia.⁵⁰ In addition, a majority of cases will remain within the 45-to-64-year age group in LMICs, whereas those older than 65 years of age are most affected in HICs.

Rising rates of obesity, and the aging and urbanization of the population, likely link to the diabetes epidemic. Nearly 90% of type 2 diabetes cases relate to obesity, and diabetes and its related complications are the costliest consequence of obesity. Mortality from diabetes is also on the rise, with approximately 4.6 million deaths in 2011.

Asian countries face a relatively larger burden of diabetes, compared with the Europe and Central Asia or Latin America and Caribbean regions. India and China, for example, have the largest numbers of diabetics in the world—61.3 million and 90 million, respectively. Asian populations may have a higher risk for developing diabetes

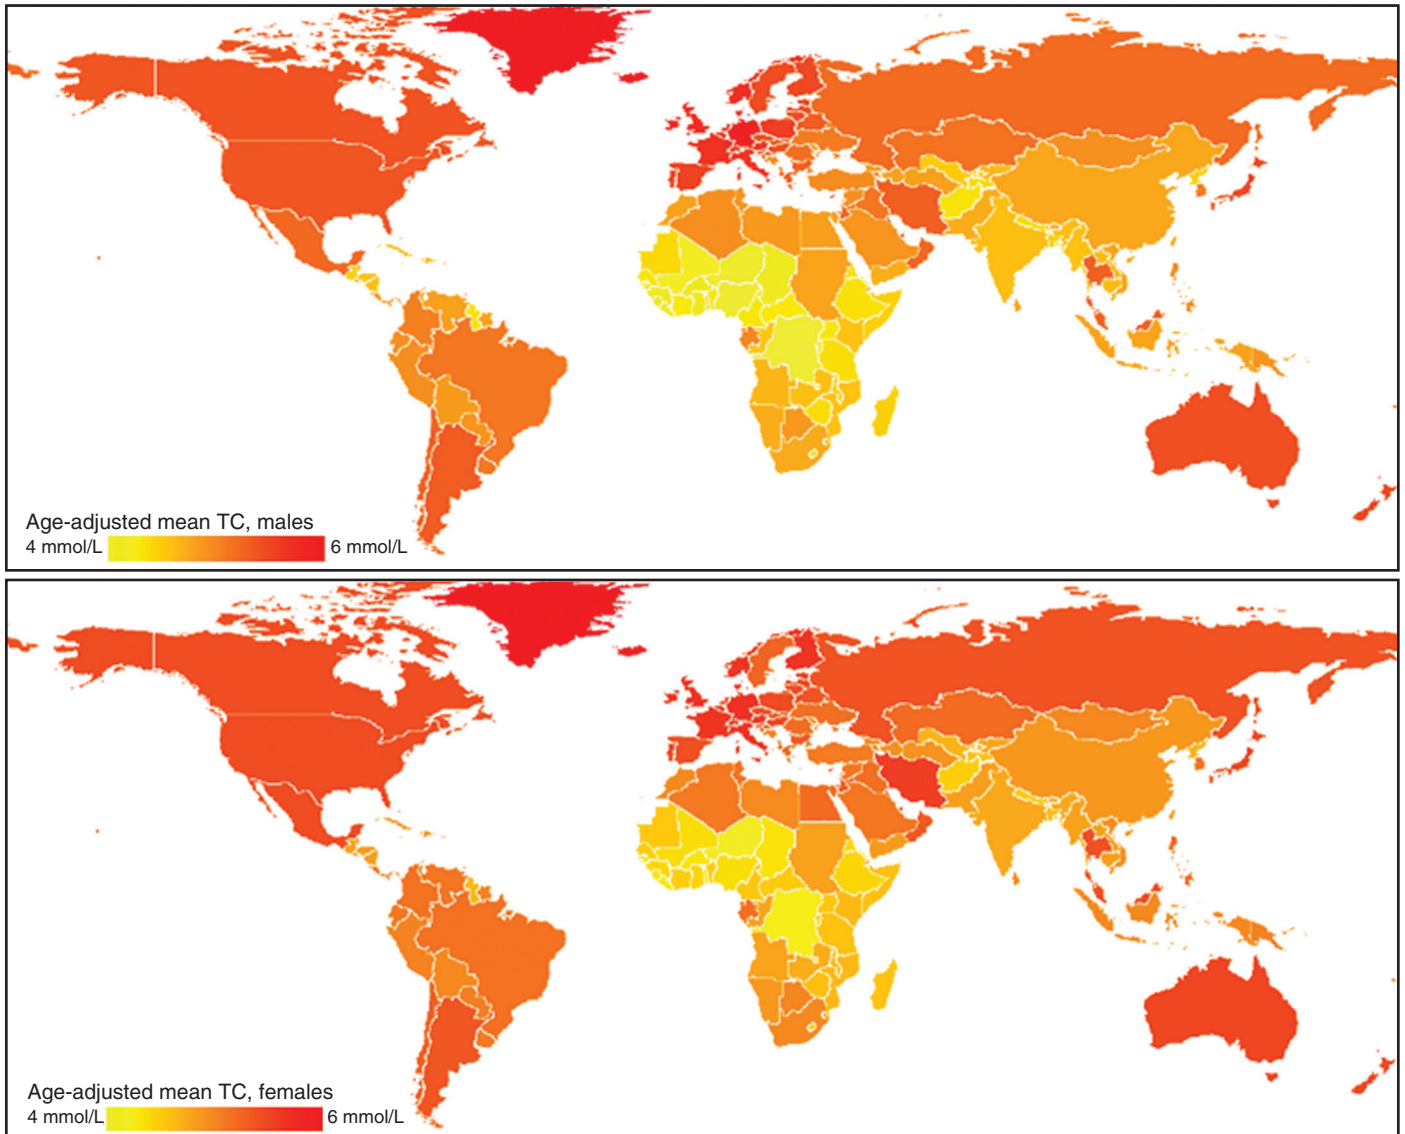

FIGURE 1-9 Age-adjusted mean total cholesterol (TC) for males (top) and females (bottom), 2008. (From Farzadfar F, Finucane MM, Danaei G, et al: National, regional, and global trends in serum total cholesterol since 1980: Systematic analysis of health examination surveys and epidemiological studies with 321 country-years and 3.0 million participants. *Lancet* 377:578, 2011.)

even at a lower BMI, because of a greater tendency toward visceral obesity. In addition, this population may experience both undernutrition (during the perinatal period) and rapid weight gain (during childhood), a combination that increases the risk for insulin resistance.⁵¹

The most recent GBD study found a global increase in mean FPG. The study analyzed multiple published and unpublished health surveys and epidemiologic studies by applying a bayesian hierarchical model for each sex by age, country, and year. Between 1980 and 2008, mean FPG increased by 0.07 mmol/L (1.26 mg/dL) per decade in men and 0.08 mmol/L (1.44 mg/dL) per decade in women. The upward trend in FPG was nearly universal.⁴⁹ In almost every region worldwide, mean FPG increased or remained unchanged; regions that displayed apparent decreases (men in the East Asia and South-east Asia region, for example) were not statistically different from flat trends (posterior probabilities of 0.80 or less).

Although some regions had unchanging mean FPG levels, other regions—including southern and tropical Latin America, Oceania, and high-income regions—experienced significant increases. The most notable region is Oceania. Between 1980 and 2008, mean FPG increased by 0.22 mmol/L per decade in men and 0.32 mmol/L per decade in women. By 2008, Oceania had the highest mean FPG for

both sexes (6.09 mmol/L for men; 6.09 mmol/L for women) and the highest prevalence of diabetes (15.5% in men; 15.9% in women) in the world.

In addition to Oceania, the Caribbean and North Africa and the Middle East have the highest mean FPG levels in the world. Between 21% and 25% of men and between 21% and 32% of women in these countries have diabetes. By contrast, men in sub-Saharan Africa and women in high-income Asia-Pacific countries had the lowest mean FPG in 2008—5.27 mmol/L and 5.17 mmol/L, respectively. The only significant decrease in mean FPG occurred in women in Singapore, where levels fell by 0.21 mmol/L per decade.

Trends in mean FPG also varied by sex. In sub-Saharan Africa, for example, mean FPG increased by 0.05 mmol/L per decade in men, but by 0.13 mmol/L per decade in women. The Central Asia, North Africa and Middle East region had similar differences in sex: mean FPG increased by 0.06 mmol/L per decade in men, and by 0.16 mmol/L per decade in women.

Obesity

Obesity is increasing throughout the world, and particularly in LMICs, where the trajectories are steeper than those in HICs. According to the latest GBD study, nearly 1.46 billion adults were overweight (BMI

FIGURE 1-10 Prevalence rates (%) for diabetes among individuals 20 to 79 years of age, 2011. (From International Diabetes Federation: *IDF Atlas*. 5th ed. Brussels, Belgium, International Diabetes Foundation, 2011 [<http://www.idf.org/diabetesatlas>].)

≥ 25 kg/m²) in 2008; of these, approximately 502 million were obese (BMI ≥ 30 kg/m²).⁵²

Explanations for this rapid trajectory are complex and include changes in dietary patterns, physical activity, and urbanization. Popkin and Garden-Larsen report that the use of edible oils, caloric sweeteners, and animal-source foods is increasing.⁵³ Annual animal food consumption tripled in China from the 1950s to 1990s. Physical activity levels are expected to decline as urbanization leads to increased use of motorized vehicles and a change to more sedentary occupations.

Unlike data from the 1980s, which showed that obesity affected predominantly the higher-income group in LMICs, a recent analysis shows a shift to the poor in the burden of overweight and obesity. Although higher-income groups still have the highest prevalence of overweight and obesity, rates are increasing faster in lower-income groups.⁵⁴ The poor have relatively more susceptibility to obesity as a developing country's GNP approaches the middle-income range.^{54,55} Higher GDP also is associated with faster rates of increase in the prevalence of overweight and obesity in lower-income groups.⁵⁴

The literature spotlights two groups: Women are more affected than men, with overweight women generally outnumbering underweight women as indicated by data from 36 LMICs.⁵⁶ In the same survey, prevalence of overweight women exceeded 20% in more than 90% of surveyed countries. Even rural areas in half of the countries surveyed exhibited such rates. Adolescents are at particular risk, with 1 in 10 children currently estimated to be overweight.^{53,57} The number of overweight children is increasing in countries as diverse as China, Brazil, India, Mexico, and Nigeria. According to the most recent WHO estimates, 40 million children younger than 5 years of age are overweight. Brazil saw an alarming rise—from 4% to 14% over a two-decade period. In 1980, the worldwide obesity prevalence rate was 4.8% in men and 7.9% in women. By 2008, prevalence rates had nearly doubled to 9.8% in men and 13.8% in women.

Globally, BMI rose in both men and women. The GBD study analyzed published and unpublished health examination surveys and epidemiologic studies (linear regressions were developed to estimate mean BMI from overweight or obesity prevalence, when available) and found that between 1980 and 2008, global BMI rose by 0.4 kg/m² per decade in men and 0.5 kg/m² per decade in women.

BMI varied substantially between regions and by sex (Fig. 1-11). In 2008, the age-standardized mean BMI in the United States was 28.5 kg/m² in men and 28.3 kg/m² in women. In contrast with the United States and other HICs with similarly high BMIs, the sub-Saharan Africa and Asia regions have some of the lowest mean BMIs. Men in Ethiopia, for example, have a mean BMI of 20.2 kg/m², and women in Bangladesh have a mean BMI of 20.5 kg/m².

The largest increase in BMI occurred in Oceania. Between 1980 and 2008, mean BMI rose by 1.3 kg/m² per decade in men and 1.8 kg/m² per decade in women. Of the islands in the Oceania region, Nauru had the largest BMI increase of more than 2 kg/m². BMI trends were similar in the North American high-income region (1.1 kg/m² per decade in men and 1.2 kg/m² per decade in women). In Latin America and the Caribbean, mean BMI for women increased 0.6 to 1.4 kg/m² per decade. By contrast, mean BMI decreased in Central African men by 0.2 kg/m² per decade and remained unchanged in South Asian men. In women, mean BMI remained static, with changes less than 0.2 kg/m² per decade in central Asia, central Europe, and Eastern Europe.

Although regional trends generally showed concordance between sexes, some exceptions occurred. There was no change in mean BMI in South Asian men, but mean BMI in women increased at a rate close to the global average, 0.4 kg/m² per decade. The most significant discrepancy in sex trends occurred in Central Africa. BMI in men in Central Africa decreased by 0.2 kg/m² per decade, the only significant decrease in any male population in the world. In women in Central Africa, on the other hand, mean BMI increased by 0.7 kg/m² per decade, a rate greater than the world average.

Diet

As humans have evolved, selective pressures have favored the ability to conserve and store fat as a defense against famine. This adaptive mechanism has become unfavorable in light of the larger portion sizes, processed foods, and sugary drinks that many people now regularly consume. Between 1970 and 2010, the average daily per capita calories in the United States increased from 2076 to 2534.⁵⁸ As per capita income increases, so does consumption of fats and simple carbohydrates, whereas intake of plant-based foods decreases. A key

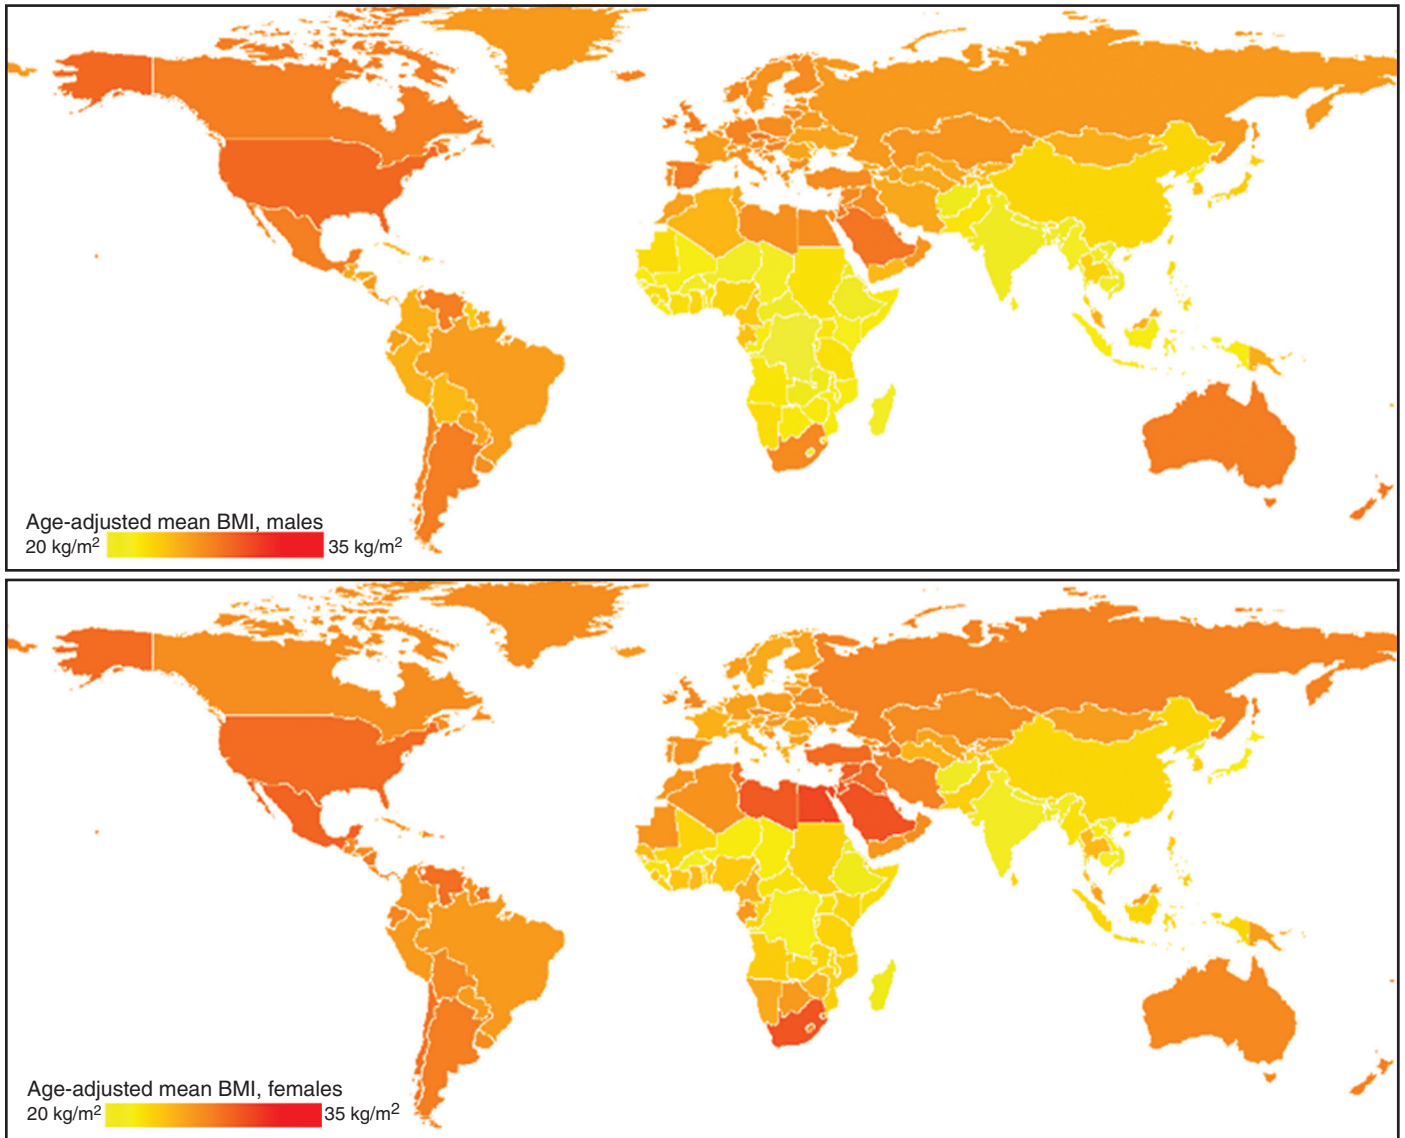

FIGURE 1-11 Age-adjusted mean body mass index (BMI) for males (top) and females (bottom), 2008. (From Finucane MM, Stevens GC, Cowan MG, et al: National, regional, and global trends in body-mass index since 1980: Systematic analysis of health examination surveys and epidemiological studies with 960 country-years and 9.1 million participants. *Lancet* 377:557, 2011.)

element of this dietary change is an increased intake of saturated animal fats and inexpensive hydrogenated vegetable fats, which contain atherogenic trans fatty acids. New evidence suggests that high intake of trans fats may also lead to abdominal obesity, another risk factor for CVD. (See Chapters 42 and 46 for further discussion of diet and CVD.)

China provides a good example of such a “nutritional transition”—rapid shifts in diet linked to social and economic changes. The China Nationwide Health Survey found that between 1982 and 2002, calories from fat increased from 25% to 35% in urban areas and from 14% to 28% in rural areas, as calories from carbohydrates fell from 70% to 47%. As recently as 1980, the average BMI for Chinese adults was about 20 kg/m², and less than 1% had a BMI of 30 kg/m² or greater. From 1992 to 2002, the number of overweight adults increased by 41%, while the number of obese adults increased by 97%.

China and other countries in transition have the opportunity to spare their populations from the high levels of trans fats that North Americans and Europeans have consumed over the past 50 years by avoiding government policies that can contribute to the CVD burden. For example, the European Union (EU) Common Agricultural Policy (CAP) program, which subsidizes dairy and meat commodities, has increased the availability and consumption of products containing

saturated fats. CAP has contributed to an estimated 9800 additional CHD deaths and 3000 additional stroke deaths in the EU, half of them premature.⁵⁹

Another facet of the nutritional transition for countries adopting a Western diet is the introduction of soft drinks and other high-sugar beverages, which are associated with weight gain and increased risk for development of type 2 diabetes. A recent study of American women shows that these beverages may be linked to CHD. Drinking full-calorie sugar-sweetened beverages on a regular basis was associated with a higher risk of CHD, even after accounting for other unhealthful lifestyle or dietary factors.⁶⁰

Physical Inactivity

In HICs, the widespread prevalence of physical inactivity produces a high population-attributable risk of cardiovascular consequences. Physical inactivity is also increasing in low- and middle-income regions of the world, where a shift from physically demanding, agriculture-based work to largely sedentary service industry-based and office-based work is occurring. A switch from physically demanding transportation to mechanized transportation accompanies this work shift.

Current guidelines call for moderate exercise for at least 30 minutes five or more days a week, or vigorous exercise for 20 minutes three days a week. Gallup's November 2011 Health and Healthcare poll found that 51.6% of adults in the United States say they exercise three or more times a week. These numbers have remained essentially unchanged since 2008. Physical inactivity levels are similarly high in other regions of the world. In the Middle East and North Africa region, for example, physical inactivity is fairly common, with a prevalence ranging from 32.9% in Syria to 56.7% in Iraq. In urban China, the proportion of adults who participate in moderate- and high-level activity has decreased significantly, whereas participation in low-level activity has increased. Between 1986 and 2006, the proportion of adults who participate in low-level activity increased from 44.8% to 66.7%.⁶¹

Of interest, the Cuban economic crisis that began in 1989 when Cuba lost the Soviet Union as a trading partner, and the resultant hardship for its people, improved their overall cardiovascular health. The crisis worsened for the next 5 years, and complete recovery did not take place until 2000. Sustained food rationing led to a reduction in per capita food intake, and the lack of public transportation resulting from fuel shortages meant that more people were walking and riding bikes. During the crisis period, the proportion of physically active adults increased from 30% to 67%, and a 1.5-unit shift in BMI distribution was observed.⁶² From 1997 to 2002, deaths attributed to diabetes, CHD, and stroke decreased by 51%, 35%, and 20%, respectively.

Other Potential Contributing Factors

Aging Demographics

Average life expectancy will reach 73 years by 2025, according to the WHO. This rise relates to a decline in overall infant mortality and fertility rates. Although older adults will constitute a greater percentage of the population in HICs—more than 20% of the U.S. population will be older than 65 years of age by 2025—low- and middle-income regions such as Asia and Latin America will nearly double their relative proportion of elderly people, to 10% of their populations.⁶³

The time of transition to an older population is sharply shorter in LMICs. For example, whereas it took the United States and Canada more than 65 years to double their over-65 population, China will do so in 26 years, Tunisia in 24, and Brazil in 21.⁶⁴ Currently, 77% of the growth in the older adult population is occurring in low-income and middle-income regions. Such acute changes in the population structure leave less time to expand an already overburdened health infrastructure to address the chronic diseases of older adults, which prominently include cardiovascular conditions.

Fetal Origins

Adverse influences, such as undernutrition during fetal life (fetal “programming”) and early postnatal life, appear to affect the prevalence of adult CVD and to contribute to its risk factors. Barker, in his “developmental origins of adult disease” hypothesis, suggested that adverse influences early in development, particularly during intra-uterine life, could result in permanent changes in the physiology and metabolism of the pancreas, kidney, muscle, and vascular endothelium, resulting in adult insulin resistance, metabolic syndrome, hypertension, and CHD.⁶⁵ Factors such as maternal adiposity, gestational weight gain, maternal nutritional deprivation, fetal exposure to an environment of maternal hyperglycemia, hypercholesterolemia, and exposure to smoking, were identified as the key initiating factors that may lead to CVD later.⁶⁶ Recent evidence indicates that the first 2 years of postnatal life are a sensitive or “critical” period of development, and any stimulus or insult during this period appears to have lasting or lifelong significance for adult-onset CVD.^{66,67} Several epidemiologic studies have demonstrated these associations, and two randomized trials from Guatemala and India on nutritional supplementation for pregnant mothers demonstrated favorable cardiovascular risk profiles among the children of mothers who received such supplementation.^{68,69} The mechanisms of increased risk appear to be

both biologic (alterations in fetal tissues and postnatal epigenetic modifications) and social (cognitive impairment, low productivity, and higher prevalence of cardiovascular risk factors among those with lower birth weight and early-life adverse influences), and the risk is further compounded by childhood obesity and sedentary habits. Thus the prevention of adverse fetal exposures and subsequent long-term consequences requires a holistic approach. An understanding of prenatal risk factors and their early childhood modifiers will provide an opportunity for prior to development of risk factors. These include improved maternal nutrition during pregnancy and lactation, emphasis on breastfeeding through early infancy, and assuring adequate balanced nutrition to infants. On the basis of our current understanding, policymakers and health care professionals should design and develop preventive strategies that effectively influence these very early determinants of CVD development.⁷⁰

ECONOMIC BURDEN

Despite some overlap, at least three approaches can measure the economic burden associated with CHD. The first source of financial burden is defined by the costs incurred in the health care system itself and reported in “cost-of-illness” studies. In these studies, the cost of CHD includes the costs of hospitalizations for angina and MI, as well as heart failure attributable to CHD. The costs of specific treatments or procedures related to CVD, such as thrombolytics, catheterization, and PCI, and the costs associated with outpatient management and secondary prevention, including office visits and pharmaceutical costs, are also included. In addition, nursing home, rehabilitation (inpatient and outpatient), and home nursing costs require consideration.

The second economic assessment is based on microeconomic studies that assess the household impact of catastrophic health events such as MI. These studies look at out-of-pocket expenses incurred by the individual patient or family that might have other downstream economic impacts, such as loss of savings or sale of property to cover medical costs. Many LMICs lack an extensive insurance scheme, and health care costs are almost entirely borne by individuals,⁷¹ so microeconomic studies to date have not considered CHD exclusively, instead looking more generally at chronic diseases overall. Furthermore, the limited data do not confirm the causality between chronic disease and individual or household poverty. Expenditures for coronary disease or its addictive risk factors such as tobacco, however, could lead to substantial and even impoverishing costs.

The third method of determining financial burden from CHD is based on a macroeconomic analysis. These assessments look at lost worker productivity, or economic growth lost by adults with CHD or their caregivers being partially or completely out of the work force because of illness. The data for the impact of chronic diseases on labor supply and productivity are more robust. An additional cost not often accounted for is the intangible loss of welfare associated with pain, disability, or suffering by the affected person. These indirect costs are often accounted for by “willingness-to-pay” analyses, asking generally how much would an individual pay to avert suffering or dying prematurely from CHD. The gains are not merely improved work performance, but also enjoying activities beyond production. Studies in the United States suggest that as much as 1% to 3% of GDP is attributable to the cost of care for CVD, with almost half of that related to CHD.⁷² In China, annual direct costs of CVD are estimated at more than \$40 billion (U.S.), or roughly 4% of GNI. In South Africa, 2% to 3% of GNI is devoted to the direct treatment of CVD, which equates to roughly 25% of South African health care expenditures. The indirect costs are estimated at more than double that of the direct costs. Although few cost-of-illness studies for CHD have been performed in other regions, such studies have reported on the financial burdens attributed to risk factors for CHD. For example, the direct costs caused by diabetes in the Latin American and Caribbean countries were estimated at \$10 billion (U.S.). Indirect costs were estimated at more than \$50 billion in 2000. The limited studies available

suggest that obesity-related diseases account for 2% to 8% of all health care expenditures in HICs. In India and China, the costs for obesity are about 1.1% and 2.1% of GDP, respectively.

Recently, the costs attributable to nonoptimal BP levels as mediated through stroke and MI were evaluated for all regions of the world.⁷³ Globally, the health care costs of elevated BP were estimated at \$370 billion (U.S.) for 2001; this amount represented approximately 10% of all global health care expenditures for that year. Regional variations do exist, with hypertension being responsible for up to 25% of health care costs in the Eastern European region (Fig. 1-12). Over a 10-year period, BP-related health care costs could equal \$1 trillion (U.S.) globally, and indirect health care costs attributed to BP could be nearly four times as much.

That a high proportion of CVD burden occurs earlier among adults of working age augments its macroeconomic impact in LMICs. Under current projections, in LMICs such as South Africa, CVD will strike 40% of adults between 35 and 64 years of age, compared with 10% in the United States. India and China will have death rates in the same age group that are two and three times that for most HICs. In view of the large populations in these two rapidly growing economies, this trend could have profound economic effects over the next 25 years, as workers in their prime succumb to CVD.

COST-EFFECTIVE SOLUTIONS

The large reductions in age-adjusted CVD mortality rates that have occurred in HICs result from three complementary types of interventions. One strategy targets those with acute or established CVD. A second entails risk assessment and targeting persons at high risk because of multiple risk factors for intervention before their first CVD event. The third strategy uses mass education or policy interventions directed at the entire population to reduce the overall level of risk factors. This section reviews various cost-effective interventions (see also Chapter 42). Much work remains undone in LMICs to determine the best strategies given limited resources, but if implemented, these interventions could go a long way toward reducing the burden. Table 1-3 lists the cost-effectiveness ratios for many high-yield interventions that could be or have been adopted in low- and middle-income regions.

Established Cardiovascular Disease Management

People at highest risk are those suffering an MI or stroke; as many as half die before they ever receive medical attention. For those who do make it to a hospital, standard medical therapies were examined in a cost-effectiveness analysis in the Disease Control Priorities Project in Developing Countries.⁷⁴

Four incremental strategies were evaluated for the treatment of MI and compared with a strategy of no treatment as a control for the six World Bank low- and middle-income regions. The four strategies compared were (1) aspirin; (2) aspirin and atenolol; (3) aspirin, atenolol, and streptokinase; and (4) aspirin, atenolol, and tissue plasminogen activator (t-PA). The incremental cost per quality-adjusted life-year (QALY) gained for both the aspirin and beta blocker interventions was less than \$25 for all six regions. Costs per QALY gained for streptokinase were between \$630 and \$730 across the regions. Incremental cost-effectiveness ratios for t-PA were around \$16,000/QALY gained, compared with streptokinase. Minor variations occurred between regions as a result of small differences in follow-up care based on regional costs.

Secondary prevention strategies are equally cost effective in LMICs. Studies show that a combination of aspirin, an ACE inhibitor, a beta blocker, and a statin for secondary prevention can lead to acceptable cost-effectiveness ratios in all low- and middle-income regions. Use of currently available generic agents, even in the absence of the so-called “polypill,” could be highly cost-effective, on the order of \$300 to \$400 per person per QALY gained.

TABLE 1-3 Cost-Effectiveness for a Selection of CHD Interventions in Developing Regions

INTERVENTION	COST-EFFECTIVENESS RATIO (\$ U.S./DALY)
Drug Treatments	
<i>Acute myocardial infarction</i>	
ASA, BB (global)	11-22
ASA, BB, SK (global)	634-734
ASA, BB, tPA (global)	15,860-18,893
Prehospital thrombolysis (Brazil)	457/LY
Secondary Treatment (CHD)	
Multidrug regimen (ASA, BB, ACEI, statin) (global)	1686-2026
Coronary artery bypass graft (global)	24,040-72,345
Primary prevention	
Cholesterol-lowering (Brazil)	441/LY
Multidrug regimen (AR >20%-25%) (global)	771-1195
Policy Interventions	
Tobacco	
Price increase of 33%	2-85
Non-Policy Interventions	
33-1432	
Salt reduction[†]	
2- to 8-mm Hg reduction	Cost saving—250
Fat-related interventions[‡]	
Reduced saturated fat intake	Cost saving—2900
Trans fat replacement—7% reduction in CHD	50-1500
Devices	
Cardioverter-defibrillators—primary prevention (Brazil)	50,345 (US\$ PPP/QALY)

ACEI = angiotensin-converting enzyme inhibitor; AR = absolute risk; ASA = aspirin; BB = beta blocker; CHD = coronary heart disease; SK = streptokinase; tPA = tissue plasminogen activator.

*Across six World Bank regions.

[‡]Range includes estimates of cost of interventions (<\$0.50-\$6.00).

Data from Gaziano TA: Cardiovascular disease in the developing world and its cost-effective management. *Circulation* 112:3547, 2005; and from Gaziano TA, Galea G, Reddy KS: Chronic diseases 2—scaling up interventions for chronic disease prevention: The evidence. *Lancet* 370:1939, 2007.

Risk Assessment

Primary prevention is paramount for the large number of people who are at high risk for acquiring CVD. In view of limited resources, finding low-cost prevention strategies is a top priority. Using prediction rules or risk scores to identify persons at higher risk in order to target specific behavioral or drug interventions is a well-established primary prevention strategy and has proved to be cost-effective in LMICs.⁷⁵ Most such scoring systems include age, sex, hypertension, smoking status, diabetes mellitus, and lipid values; some also include family history.^{76,77} Recently, many investigators have examined whether additional laboratory-based risk factors can add to predictive discrimination of the risk factors used in the Framingham Heart Study risk score. The recent analyses in the Atherosclerosis Risk in Communities (ARIC) Study⁷⁸ and the Framingham Offspring Study^{79,80} suggested that little additional information was gained when other blood-based novel risk factors were added to the traditional risk factors. Although the Reynolds risk score⁸¹ for women—which added family history, C-reactive protein (hsCRP), and hemoglobin A_{1c} levels—had only a marginally higher C-statistic (0.808) than the Framingham covariates (0.791), it correctly reclassified many persons at intermediate risk (see also Chapters 10 and 42 in this regard). Some women deemed to be at low risk by the Framingham risk score were reclassified as being in the intermediate or high risk category according to the Reynolds risk score, and thus would have been eligible for more aggressive management. Conversely, some women who were initially at high risk according to the Framingham criteria were reclassified as being at lower risk, and thus would not have needed treatment. Coronary artery calcium scoring may add the most in terms of changes in C-statistic or the net reclassification improvement (NRI) in intermediate-risk populations, but it has limitations as a screening strategy (see Chapter 42).⁸²

More attention is now focused on developing risk scores that would be easier to use in clinical practice, without loss of predictive discrimination in resource-poor countries. In HICs, a prediction rule that requires a laboratory test is an inconvenience; in LMICs with limited testing facilities, it may be too expensive for widespread screening, or the cost may preclude its use altogether. In response to this concern, the WHO recently released risk prediction charts for the different regions of the world, with and without cholesterol data.^{83,84} A study based on the U.S. National Health and Nutrition Examination Survey (NHANES) follow-up cohort demonstrated that a non-lab-based risk tool that uses information obtained in a single encounter (age, systolic BP, BMI, diabetes status, and smoking status) can predict CVD outcomes as well as one that requires lab testing, with C-statistics of 0.79 for men and 0.83 for women that were no different from those obtained using the Framingham-based risk tool.⁸⁵ Furthermore, the results of goodness-of-fit tests suggest that the non-laboratory-based model is well calibrated across a wide range of absolute risk levels and without changes in risk classification. The ankle-brachial index (ABI) also appears to add to risk discrimination and improve the NRI as an alternative noninvasive tool.⁸²

Policy and Community Interventions

Education and public policy interventions that have reduced smoking rates, lowered mean BP levels, and improved lipid profiles are recognized to contribute to reduction in CHD rates.⁴ Education and policy efforts directed at tobacco consumption have contributed substantially to the reductions in CVD. In addition, salt and cholesterol reduction has been evaluated as a cost-effective strategy to reduce stroke and MI in LMICs by WHO investigators.⁸⁶ Community interventions have reduced levels of multiple risk factors and, in some cases, CHD mortality (see also Chapter 42).

Tobacco Use

Tobacco control can be conceptualized in terms of strategies that reduce the supply of, or demand for, tobacco. Most public health and clinical strategies to date focus on reducing demand through economic disincentives (taxes), health promotion (media and packaging

efforts), restricted access (to advertising and tobacco), or clinical assistance for cessation. The WHO effort to catalyze the creation of a global treaty against tobacco use was a key milestone. In May 2003, the WHO World Health Assembly unanimously adopted the WHO Framework Convention on Tobacco Control (FCTC), the first global tobacco treaty.⁴¹ The FCTC had been ratified by 168 countries as of April 2009, making it one of the most widely embraced treaties in the United Nations.⁴¹ The FCTC has spurred efforts for tobacco control across the globe by providing both rich and poor nations with a common framework of evidence-based legislation and implementation strategies known to reduce tobacco use.

Jha and colleagues presented a landmark analysis of tobacco control cost-effectiveness in 2006.⁸⁷ They calculated the reductions in future tobacco deaths as a result of a range of tax, treatment, and non-price interventions among smokers alive in 2000. They found that a 33% price increase would result in a reduction of between 19.7 million and 56.8 million (5.4% to 15.9% of total) deaths in smokers from the developing world who were alive in 2000.⁸⁷ Calculations show that nicotine replacement therapy (NRT) could reduce the number of deaths by between 2.9 million and 14.3 million (0.8% to 4.0% of total) in the 2000 cohort.⁸⁷ A range of nonprice interventions such as advertising bans, health warnings, and smoke-free laws would reduce deaths by between 5.7 million and 28.6 million (1.6% to 7.9% of total) in that cohort.⁸⁷ These reductions would translate into developing world cost-effectiveness values of between \$3 and \$42/QALY saved for tax increases (not including tax revenue), \$55 to \$761/QALY for NRT, and \$54 to \$674/QALY for nonprice measures.⁸⁷

Critically important for patients who have had a coronary event, smoking cessation saves lives at a greater rate than any individual medical treatment. Mohiuddin and associates conducted a randomized controlled trial of a behavioral and medication smoking cessation program for smokers who were hospitalized with a coronary event in the critical care unit.⁸⁸ These investigators observed nearly threefold higher quit rates and a decrease in all-cause mortality at 1 year by an absolute risk of 9% (77% reduction in relative risk). This reduction corresponded with a number needed to treat (NNT) of 11 for smoking cessation to prevent 1 death in the year after a major coronary cardiac event.⁸⁸ This NNT for secondary prevention is more favorable than that for statins, beta blockers, or even aspirin.⁸⁹

Salt and Lipid Reductions

The cost-effectiveness analyses on salt reduction achieved as a result of public education are quite favorable.^{90,91} The intervention ranges from being cost-saving to \$200/DALY averted. The results of a campaign for reducing saturated fat and replacing it with polyunsaturated fat was also likely cost-effective. In the base case, a 3% decline in cholesterol and a \$6 per capita education cost were assumed. Findings included a cost as low as \$1800/DALY averted in the South Asia region, and up to \$4000/DALY averted in the Middle East and North Africa region. If the cost for the education plan were halved, however, the ratio is approximately \$900/DALY, which would be cost-saving if the reduction could be achieved for under \$0.50 per capita—a possibility in areas with less expensive access to media.

Community Interventions

In the 1970s and 1980s, a series of population-based community intervention studies were conducted to reduce risk factors for chronic disease, and are reviewed elsewhere.⁹² These studies focused on changes in health behaviors or risk factors such as tobacco use, body weight, cholesterol, and BP, as well as a reduction in CVD morbidity and mortality. In general, they included a combination of community-wide actions and those focused on persons identified as being at high risk for CVD-related health problems.

One of the earliest and most often-cited community interventions is the North Karelia project in Finland, begun in 1972. The community-based interventions included health education, screening, a hypertension control program, and treatment. Over the first 5 years of the study, reductions in risk factors occurred, along with a decline in CHD mortality by 2.9% per year—versus a 1% per year decline in the rest of Finland. During the next 10 years, declines were greater in the

rest of Finland. Over a follow-up period of 25 years, a large decline in CHD occurred in both the North Karelia region (73%) and the rest of Finland (63%). Although the overall difference in the decline in CHD deaths was not significantly greater in the study area of North Karelia, the reduction in tobacco-related cancers in men was significant. A similar study in the Stanford, California, area showed reductions in risk factors—cholesterol (2%), BP (4%), and smoking rates (13%)—compared with sites without the intervention, but no impact on disease endpoints.

Later, community interventions in HICs showed mixed results, with some showing improvements in risk factors beyond the secular decline that was occurring throughout most HICs and others exhibiting no additional decline. A meta-analysis of the randomized multiple risk factor interventions, however, showed net significant decreases in systolic BP (4.2 mm Hg), smoking prevalence (4.2%), and cholesterol (0.14 mmol/L).⁹³ The declines in total and CHD mortality of 3% and 4% were not significant. All of these projects are limited by the challenge of detecting small changes that, on a population level, may be significant—a 10% reduction in mortality could have been missed.⁹³

Several community intervention studies have been conducted in LMICs, including China, Mauritius, and South Africa. The Tianjin project showed reductions in hypertension and obesity. The Mauritius project, among other interventions, resulted in a government-led program that changed the prime cooking oil from a predominantly saturated fat palm oil to a soybean oil high in unsaturated fatty acids. Overall total cholesterol levels fell 14% during the 5-year study period from 1987 to 1992. Changes in other risk factors were mixed with declines in BP and smoking rates and increases in obesity and diabetes. The Coronary Risk Factor Study in South Africa compared a control community with two communities receiving interventions at two different levels of intensity. The interventions included mass media messages, group sponsored educational sessions, and BP screening and follow-up with the health sector when appropriate. Both high-intensity and low-intensity interventions resulted in improvements in BP, smoking rates, and HDL-to-total cholesterol ratio over the control community, but with little difference between the two intervention communities.

Another significant reduction in CHD came not through a concerted community intervention but through changes in fiscal policy. In Poland, reductions in subsidies for animal products such as butter and lard led to a switch from saturated to polyunsaturated fats, mainly rapeseed-based and soybean-based oils. The decrease in CHD mortality by more than 25% between 1991 and 2002 could not be explained by increased fruit consumption or decline in smoking rates. Success stories such as in Poland and Mauritius are rare, however, suggesting the challenges to achieving meaningful changes targeting single risk factors at a national level.

SUMMARY AND CONCLUSIONS

CVD remains a significant global problem. The swift pace of economic and social transformation in a postindustrial world with rapid globalization presents a greater challenge for low- and middle-income economies than for high-income economies. Although CVD rates have declined in HICs, they are increasing in virtually every other region of the world. From a worldwide perspective, the rate of change in the global burden of CVD is accelerating, reflecting the changes in the low- and middle-income economies, which represent 85% of the world's population. This preventable epidemic will have substantial consequences on many levels: individual mortality and morbidity, family suffering, and staggering economic costs—both the direct costs of diagnosis and treatment and the indirect costs of lost productivity.

Different regions of the world face different stages of the epidemic. In HICs, managing an ever-older population with chronic manifestations of CVD such as heart failure will strain health care budgets. Currently, the Eastern European countries and members of the former Soviet Union face enormous burdens, with more than half of all

deaths attributed to CVD. Meanwhile, countries in sub-Saharan Africa are just beginning to see increases in these chronic illnesses while still grappling with HIV/AIDS. No single global solution to the rising burden of CVD exists, in view of the vast differences in social, cultural, and economic circumstances. HICs must minimize disparities, reverse unfavorable trends in CVD risk factors and behaviors, and deal with the increasing prevalence of CVD in an aging population. The most complex challenges face LMICs—with increasing access to low-cost tobacco products and ready access to less than favorable dietary options. Preventing the poverty-inducing effects of catastrophic CVD events will require efforts to improve access to low-cost prevention strategies at both the societal and the individual level.

A reduction in the disease burden would similarly require both policy and personal changes. In the long run, the allocation of resources to lower-cost strategies will likely prove more cost-effective than dedicating resources to high-cost management of CVD. From a societal perspective, efforts to strengthen tobacco control strategies, improve dietary choices, and increase physical activity will be paramount. At the personal level, risk assessment strategies and treatment modalities require simplification. Furthermore, alternative deployments of allied health workers such as community health workers will need evaluation, in view of the limited human resources in most LMICs. HICs must share with leading and emerging middle-income countries the burden of research and development into every aspect of prevention and treatment. Through further expansion of the knowledge base, particularly regarding the economic consequences of various treatment and prevention strategies, the efficient transfer of low-cost preventive and therapeutic strategies may alter the natural course of the epidemiologic transition in every part of the world, thereby reducing the excess global burden of preventable CVD.

CHANGING DEMOGRAPHICS OF THE U.S. POPULATION

Cardiovascular disease (CVD) and stroke remain the leading causes of death and disability in the United States. These illnesses afflict the entire U.S. population. In the past, data extracted from large epidemiologic studies and major clinical trials with racially homogeneous cohorts were used to assess risk and describe the natural history of CVD, but the generalizability of these risks and disease traits to a more heterogeneous populace (i.e., varied populations) has been confirmed in contemporary population surveys that are racially and ethnically diverse. The risk for heart disease and stroke is ubiquitous and affects all populations. However, current data suggest that the racial or ethnic attributes of CVD may vary significantly among populations. Given the consequences of heart disease, it is imperative that the practice of cardiovascular medicine address the nuanced risk profiles and different manifestations of disease within varied populations. The emerging importance of these varied populations is directly related to the changing U.S. demographics. Currently, 14% of the U.S. population is black and 16% is Hispanic, and the Asian cohort is growing rapidly.¹ When added to the Native American population, the aggregate representation of these varied populations now approaches 40%, and a majority population in the United States will probably no longer exist by 2050 (**Fig. 2-1**). Accordingly, cardiovascular physicians and scientists must be aware of the epidemiology, pathophysiology, and treatment of heart disease in varied U.S. populations.

DISTRIBUTION OF KNOWN RISK FACTORS FOR HEART DISEASE

The incidence of known risk factors for CVD varies considerably by race and ethnicity (see **Chapters 42, 43, and 60**). The Third National Health and Nutrition Examination Survey (NHANES III) contains data on the distribution of hypertension in non-Hispanic white, non-Hispanic black, and Hispanic groups. Hypertension affects at least 33 million whites, almost 6 million blacks, and 1.3 million Hispanics. The rate of hypertension in blacks is approximately 40% (among the highest in the world); in whites, 25.6% in men and 23.8% in women; and in Hispanics, 14.6% in men and 14% in women. Worse disease severity accompanies a higher prevalence of hypertension in blacks. The prevalence of stage 3 hypertension ($>180/110$ mm Hg) is 8.5% in blacks versus 1% in whites. Mean systolic and diastolic blood pressure (BP) in blacks is 125/75 mm Hg and 122/74 mm Hg in whites. For hypertensive blacks, the difference in BP versus that in normotensive blacks is 30/20 mm Hg, whereas for hypertensive whites, the difference in BP is 23/15 mm Hg.²

Diabetes, a deadly risk factor for CVD, currently affects 17 million Americans. The incidence of the disease has increased 49% in the last decade, probably because of the increased incidence of obesity. Blacks have the highest prevalence of hemoglobin A1c: 7% or greater. In individuals 40 to 74 years of age, the prevalence of diabetes is 11.2% in whites, 18.2% in blacks, and 20.3% in Hispanics. Despite the higher incidence of diabetes in Hispanics, mortality rates from diabetes are highest in blacks—28.4/100,000 for men and 39.1/100,000 for women. This compares with 23.4/100,000 and 25.7/100,000 for white men and white women, respectively.³ Hypertension occurs concomitantly in 75.4% of blacks with diabetes, 70.7% of Hispanics with diabetes, and 64.5% of whites with diabetes. Insulin resistance, along with obesity, hypertension, and dyslipidemia, constitutes the metabolic syndrome, which is associated with excessive CVD. Applying the National Cholesterol Education Program Adult Treatment Panel III (NCEP ATP III) criteria to the NHANES III database, the incidence of metabolic syndrome might exceed 30% in the U.S. population older than 20 years but increases to greater than 40% in older adults and is highest in the varied populations.⁴⁻⁶

Hispanics have the highest incidence of metabolic syndrome—31.9% overall and 35% in Hispanic women. Despite the high incidence of insulin resistance and metabolic syndrome, Hispanics have a lower prevalence of hypertension than blacks do. When the influence of obesity, body fat distribution, and insulin concentration is followed prospectively in whites and Hispanics, each factor is independently associated with the development of hypertension—with the greatest risk in subjects with the highest body mass index (BMI; >30 kg/m²) and the highest insulin concentration (>95 pmol/L). There appears to be no additional risk for CVD in Hispanics as compared with whites.⁷

The incidence of overweight or obesity (BMI >25 kg/m² being defined as overweight, >30 kg/m² as obese, and >40 kg/m² as morbidly obese) is growing in the U.S. population, and the varied populations are affected disproportionately. The prevalence of overweight and obesity is probably 60% or higher in the United States, and a third of all children and adolescents are overweight or obese.² The prevalence of both overweight and obesity is higher in blacks than in whites and higher in Hispanics than in whites. The mean BMI is 29.2 kg/m² in blacks, 28.6 kg/m² in Hispanics, and 26.3 kg/m² in whites. Black women are on average 17 lb heavier than white women of comparable age and socioeconomic status. Six of the 15 states with the highest prevalence of hypertension are located in the southeastern part of the United States (corresponding to the “stroke belt”), and half of all blacks live in this region. The highest prevalence of obesity, 44%, is found in black women, and in the southeastern United States a striking 71% of black women are obese.^{8,9} Although Asians have lesser rates of overweight and obesity, standard BMI weight class definitions may be inappropriate for this population. Dyslipidemia is an important modifiable risk factor for heart disease in the United

FIGURE 2-2 **A**, Age-adjusted death rates for coronary heart disease by race/ethnicity and sex in the United States (2008). **B**, Age-adjusted death rates for stroke by race/ethnicity and sex in the United States. (From National Heart, Lung and Blood Institute. *Morbidity & Mortality: 2012 Chart Book on Cardiovascular, Lung, and Blood Diseases*. Bethesda, Md, NHLBI, 2012.)

States, and treatment of lipid disorders decreases the incidence of heart disease. Several reports have suggested that blacks have lower low-density lipoprotein (LDL) cholesterol concentrations and less hypercholesterolemia than whites do. The CARDIA (Coronary Artery Risk Development in Young Adults) study identified the prevalence of high LDL cholesterol levels in young adults; LDL cholesterol exceeded 160 mg/dL in 10% and 5% of young black men and women, respectively, as opposed to 9% and 4% of young white men and women. High-density lipoprotein cholesterol levels were higher in black men than in white men.⁸ Levels of lipoprotein(a), a known risk factor for coronary heart disease (CHD) (see Chapter 45), are twofold to threefold higher in blacks.

CORONARY HEART DISEASE

The United States is among the high-income countries that have experienced steep declines in CHD-related mortality since 1968.^{10,11} The decline in mortality is attributed both to improved management of risk profiles and to treatment strategies. Rosamond and colleagues¹² found that over a period of 22 years (1987 to 2009), CHD mortality

and incident myocardial infarction (MI) declined significantly in four U.S. communities, with the steepest declines occurring in the second decade. Declines were significant in both black and white Americans in the cohort; however, the magnitude of decline was less in black Americans. Similar findings were noted by Chen and coworkers¹³ in a Medicare cohort. Comparing U.S. mortality data from 1980 and 2000, Ford and associates⁵ estimated that 47% of the decrease in mortality was attributable to treatments whereas 44% was attributable to improved risk factor control, including reduced total cholesterol, decreased systolic BP, decreased smoking, and increased physical activity. In this same period, however, the authors estimated that the increasing prevalence of obesity and diabetes resulted in a small increase in the number of deaths (8% and 10%, respectively).³

Even though risk factors and mortality from CHD have been declining in the United States, both still vary considerably by U.S. racial and ethnic groups (Fig. 2-2). These groups are classified by race (white, black American, Native American/Alaskan Native, and Asian) and by Spanish language grouping (Hispanic). In the United States there are significant admixtures of populations by racial groups, as well as racial heterogeneity among Spanish language groups. Although these broad categories are used to examine population-based

cardiovascular risk profiles, disease patterns, and outcomes, they are not independent of socioeconomic, psychosocial, genetic, epigenetic, and other determinants of CHD. Nonetheless, there are population-associated differences in CHD risk profiles, disease patterns, and outcomes that can and should be used to better understand the pathophysiology of CHD, to assist in targeted disease reduction strategies, and to improve outcomes across all U.S. population groups.

Risk for Coronary Heart Disease and Mortality in U.S. Hispanics. In the United States, Hispanic groups are the minority group with the most rapid increase in population; they originate from various countries, including Mexico (the largest number of U.S. Hispanics), the Caribbean Islands (Puerto Rico, Cuba, and the Dominican Republic), and Central and South America. Contemporary U.S. Hispanic populations have varying proportions of ancestral admixture of European, black, and Native American descent, depending on their country of origin.¹⁴⁻¹⁸ Even though population health data are often collected by Spanish language group, it is important that studies addressing risk and outcomes in Hispanics take into consideration the heterogeneity in this population.¹⁹ In MESA (Multi-ethnic Study of Atherosclerosis)¹⁵ and in the Hispanic Community Health Study,¹⁹ those of Hispanic origin were further subdivided by geographic locus of family origin into Mexican American, Dominican American, Puerto Rican American, and other. The prevalence of risk factors differed significantly in the four groups, and the association between risk factors and measures of subclinical CHD also varied significantly. Mexican Americans had the highest levels of subclinical measures of CHD, with Puerto Rican Americans having the next highest levels despite distinctly different risk profiles between the groups.¹⁵ Consistent with other immigrant populations, lower socioeconomic status and greater acculturation were associated with greater risk for CHD. Overall, however, the prevalence of CHD and stroke by self-report was low (4.2% and 2.0% for men, 2.4% and 1.2% for women).

Coronary Heart Disease in Black Americans. As shown in Figure 2-2, black American men and women have the highest age-adjusted mortality from CHD of all the racial/ethnic groups in the United States.²⁰ Rosamond and colleagues¹² found that between 1987 and 2008, CHD-related mortality in four U.S. communities declined significantly, with the steepest declines occurring in the second decade. Declines in CHD mortality were significant in both black and white Americans; however, the magnitude of the decline was less in blacks. Similar findings were reported by Chen and coauthors¹³ in a Medicare cohort. Ford²¹ examined trends in risk for CHD in 7800 participants in NHANES between 1999 and 2010 and found that risk for CHD declined significantly in men and whites, declined nonsignificantly in Mexican Americans, and increased nonsignificantly in black Americans. Although black and white men have been found to have a similar incidence of total CHD, black men had a greater incidence of fatal CHD. Black women had a higher incidence of both total CHD and fatal CHD than white women did. Importantly, although BP, total cholesterol, and smoking status improved in the cohort overall, no significant improvement in BP or total cholesterol occurred in black Americans and an increased prevalence of diabetes was noted in this group. Of interest, even though mortality from CHD is higher in black than in white Americans, at coronary angiography blacks have been found to have less obstructive coronary disease^{22,23} and differences in the anatomic distribution of coronary lesions. Significant differences have been identified in the number and type of risk factors for CHD between black and white Americans.²⁴ In 2010, 58% of blacks had at least one risk factor versus 47% of whites and 45% of Mexican Americans. Lifetime risk for CVD across all population groups has been found to be dependent on the number of risk factors present in each age and race group and thus may in part explain the greater mortality in blacks.

Even though the burden of risk factors for CHD is substantially greater in black Americans, when risk factors are controlled, outcomes are improved irrespective of race. Yang and coworkers²⁵ studied the impact of achievement of ideal measurements of seven CVD health metrics in 45,000 U.S. subjects over a 22-year period. Across all racial groups, the more of these CVD risk metrics that were at ideal measurement, the lower the risk for mortality from CHD. Elevated BP, a risk factor notably more prevalent in black Americans at younger ages, was associated with the highest risk for mortality from CVD.

Coronary Heart Disease in Asian Americans. Asian Americans account for a smaller percentage of U.S. minority populations but are analogous to Hispanics with respect to heterogeneity in national origin and parameters such as U.S. or foreign born, duration of U.S.

residence, English language fluency, level of education, and income. Included in this group are individuals of Asian Indian, Chinese, Filipino, Korean, Japanese, Vietnamese, and other Asian backgrounds. Health statistics often group Asians as a single group; however, this practice obscures distinctive CVD risk profiles, as well as differences in outcomes.²⁶ U.S. data comparing the CHD risk profiles of Asians grouped together found that overall risk for CHD is lower than that for other racial/ethnic groups but that risk factors varied by the specific Asian subgroup and that the pattern of vascular disease associated with risk also differed.²⁶ Although less likely than U.S. whites to smoke or have increased BMI, the prevalence of metabolic syndrome has been found to be higher in Asian Americans than in non-Hispanic whites and is identified at a lower BMI.²⁶ This has been noted particularly in Asian Indians, who have been found to have higher rates of insulin resistance, diabetes, and dyslipidemia; greater waist circumference; and higher plasma concentrations of procoagulants²⁶ than whites do. Rates of hospitalization for CHD have been reported to be higher in Asian Indians than in whites and lower in Chinese Americans than in whites. By contrast, the incidence of hemorrhagic stroke is higher than that of MI in Japanese and Chinese Americans. Stroke prevalence in these two groups has been reported to decrease with longer duration of U.S. residency.

Coronary Heart Disease in American Indians and Alaskan Natives. Despite being the smallest population subgroup in the United States (1.5%), the prevalence of risk factors for CHD in American Indians/Alaskan Natives has risen dramatically since the 1970s. Diabetes, elevated cholesterol, and smoking are now more prevalent in Native Americans than in whites, black Americans, and Hispanics. Rates of CHD and CHD mortality have also risen and now exceed rates in the general population. Declines in heart disease and stroke mortality have also been nonsignificant in this population in comparison to non-Hispanic whites. Of importance, mortality from heart disease and stroke is much more likely to occur at 65 years or younger in this population. Reasons for the increase in the incidence of CVD, as well as mortality, are multifactorial and include decreases in deaths from infectious diseases; an increased prevalence of diabetes, hyperlipidemia, tobacco abuse, and obesity; geographic isolation; poor access to health care; high psychosocial stress; and a poorly functioning health system.

Racial/Ethnic Differences in Health Care for Coronary Heart Disease

In addition to differences in CHD risk burden and patterns of vascular disease, significant differences in care, including risk assessment, risk management, and treatment of acute CHD, exist when blacks, Hispanics, and American Indians are compared with non-Hispanic whites.²⁷ Asians with acute coronary syndromes undergo diagnostic and therapeutic procedures at equivalent rates as non-Hispanic whites and have equivalent in-hospital mortality and reinfarction rates.²⁶ Blacks are less likely to be referred for cardiovascular specialty consultations, are less likely to undergo revascularization after acute MI, even with adjustment for severity of illness, and continue to experience higher long-term mortality.²⁷⁻³⁰ Racial and ethnic minority patients are more likely to be hospitalized at institutions with worse outcomes, are less likely to survive in-hospital cardiac arrest,^{29,30} and are more likely to undergo coronary artery bypass grafting procedures by surgeons with higher risk-adjusted mortality rates.³¹ Socioeconomic disadvantage explains some, but not all of the ongoing disparity in care.³² Cromwell and colleagues³³ examined the use of cardiovascular technologies and outcomes in Medicare beneficiaries and found that blacks and Native Americans were much less likely to undergo invasive diagnostic and therapeutic procedures despite similar insurance benefits. Although disparities in CVD outcomes are multifactorial in origin and require multidisciplinary interventions, it is clear that organizational quality improvement initiatives have a significant impact on chronic disease measures in all patients and can result in diminution in disparities between groups.³⁴ Treatment of acute MI in hospitals participating in the Get with the Guidelines—Coronary Artery Disease Program was improved across all racial/ethnic groups. A meta-analysis³⁵ of studies linking use of guideline-recommended therapies with CVD outcomes demonstrated a strong relationship between adherence to guidelines/performance measures and improved patient outcomes.

HYPERTENSION

Epidemiology

Race and ethnicity substantially influence the prevalence, impact, and control of hypertension in the U.S. population. In the United States, hypertension is more common, is more severe, develops at an earlier age, and leads to more clinical sequelae in blacks than in age-matched non-Hispanic whites.³⁶ Prevalence rates in Mexican Americans are lower than those in black Americans and comparable to those in non-Hispanic whites, but BP control rates in Mexican Americans and Native Americans are lower than in both non-Hispanic whites and black Americans (Table 2-1). Among Hispanics, higher hypertension prevalence rates have been reported in Hispanics of Puerto Rican background.^{36,37}

The increased prevalence and severity of hypertension in black Americans and other ethnic minority groups are also associated with higher rates of morbid and mortal cardiovascular and renal disease events.³⁷ Hypertension-related mortality is approximately three times higher in black than in white Americans. Age-adjusted stroke mortality is approximately 50% higher in black Americans than in other U.S. ethnic groups (Fig. 2-2B). Other ethnic minorities, such as Native Americans and Hispanics, also have a twofold to fourfold higher prevalence of end-stage renal disease (ESRD) than whites do.³⁸ In 2010, black Americans accounted for almost 37% of the entire ESRD population, a rate 3.4 times higher than that in whites. Although hypertension has dropped to the second leading cause of ESRD after diabetes in black Americans, adjusted incident ESRD rates per million population secondary to hypertension were six times greater in black Americans (46/million) than in whites (7.6/million). Rates were 15.1/million in Hispanics, 6.3/million in Native Americans, and 10.8/million in Asians. The excess ESRD rate in black Americans may be linked to a specific genetic haplotype not found in other subgroups.

Racial/Ethnic Differences in the Pathophysiology of Hypertension

The cause of essential hypertension remains elusive, as does the explanation for population differences in hypertension. Many mechanisms have been proposed to account for the earlier onset, greater severity, and increased morbidity of hypertension in black Americans (see Table 2-2)³⁷⁻³⁹; however, no single mechanism is fully explanatory, and it is likely that the ethnic differences in hypertension are multifactorial.

Genetic Versus Socioeconomic Status. The contribution of genetics to hypertension in black Americans, as in the general population, is a subject of intense investigation. Hypertension appears to be highly heritable with a multigenetic pattern of heritability, and BP heritability is estimated to be approximately 30% to 40%. However, in studies of populations of European descent, in which 16 functional genetic variants have been identified, genetics has been shown to account for only a small fraction of phenotypic BP variability (<5 mm Hg).³⁹ As in other racial/ethnic groups, no major gene or gene

TABLE 2-2 Proposed Mechanisms for the Increased Incidence of Hypertension in Blacks

Genetic susceptibility
Socioeconomic status
Renal and cellular salt handling
Dietary Na/K
Alterations in renin-angiotensin-aldosterone system
Vasodilator deficiency
Increased sleep apnea
Low birth weight

family has been identified that is directly linked to hypertension in black Americans. However, genetic variants in the chromosome 22q region (*APOL1* gene) have been shown to contribute significantly to black Americans' excess risk for ESRD, which has been attributed to hypertensive, diabetic, focal segmental glomerulosclerosis and human immunodeficiency virus-associated nephropathy.^{40,41} Socioeconomic status has received considerable attention, and studies controlling for (or minimizing) differences in socioeconomic status report reduced racial/ethnic differences in the epidemiology of hypertension and its morbidity/mortality. The effect of socioeconomic status on health outcomes is complex, and the gross estimates provided by current markers (e.g., income, education, employment, insurance status, place of residence) probably oversimplify its significance.

Salt Metabolism. Racial differences in renal salt handling have also been proposed as a potential explanation for the increased incidence and severity of hypertension in black Americans versus non-black American populations, as well as the favorable responses of hypertensive black Americans to diuretic therapy. Although salt sensitivity is more common in hypertensive black Americans, it is also very common (>50%) in other populations, and the increased salt sensitivity in black Americans may be explained at least in part by differences in disease onset, severity, concomitant diseases, or dietary patterns. A major limitation of many studies reporting racial differences in salt sensitivity is failure to adequately control for differences in age, severity of hypertension, renal function, BMI, and BP variability because these characteristics may alter rates of salt sensitivity. In a study in which groups were closely matched for sex, age, renal function, hypertension status, and weight, no racial difference in the prevalence of salt sensitivity was seen.⁴² However, the magnitude of increase in BP in response to salt loading in this study was found to be greater in black than in white American hypertensive individuals, although not in normotensive subjects, thus suggesting that the increased salt sensitivity may be a consequence rather than a cause of the hypertension. Another suggested defect in salt handling related to altered Na⁺ transport has been proposed. Higher intracellular Na⁺ has consistently been reported in black Americans more than in whites, as well as up to a 30% depression in Na⁺,K⁺-adenosine triphosphatase pump activity. Elevated intracellular Na⁺ can trigger a cascade of compensatory events leading to elevated intracellular Ca²⁺, increased vascular reactivity, and eventual BP elevation.⁴⁰

Neurohormonal Activation. Differences in the expression and activity of a variety of neurohumoral factors, particularly of the renin-angiotensin system (RAS), have been described in black versus white Americans to explain the higher incidence and severity of hypertension. Many studies have reported suppressed activity of the

renin-angiotensin-aldosterone system (RAAS) in black Americans as opposed to whites in response to changes in intravascular volume or BP. Thus hypertension in black Americans is usually classified as low renin and is generally associated with a diminished response to anti-hypertensive drugs that inhibit the RAAS. Increased levels of the pressor peptide endothelin-1 have been reported in hypertensive black Americans, with circulating endothelin-1 levels being almost eightfold higher than in normotensive black Americans and almost fourfold higher than in white hypertensives.³⁸ Furthermore, increased cardiovascular reactivity and higher circulating levels of endothelin-1 in response to acute physical or mental stress have been reported in adolescent males with a family history of hypertension. In contrast, lower levels of endogenous vasodilators such as kallikrein, atrial natriuretic peptide, prostacyclin, and nitric oxide have been reported in hypertensive black Americans.^{36,43,44} Regardless of BP, black Americans have been found to excrete less urinary kallikrein than whites do. Markedly reduced levels of atrial natriuretic peptide during salt loading have been reported in children of hypertensive versus normotensive parents, and salt-sensitive black Americans have been found to exhibit a paradoxical decrease in atrial natriuretic peptide in response to increased dietary salt intake. Rigorous assessment of the relative roles of these systems in the pathogenesis of hypertension in individuals of African ancestry remains to be carried out.

Low Birth Weight. Epidemiologic studies have raised the possibility that low birth weight (LBW) may influence disease later in life, and the increased prevalence of hypertension in blacks has been attributed to a higher incidence of LBW with an associated nephron deficit acquired in utero that does not recover after birth and leads to glomerular sclerosis, increased salt sensitivity, and subsequent hypertension.^{36,45} In a study of almost 5000 persons, a statistically significant inverse relationship was found between systolic BP and birth weight at all ages beyond birth. By the age of 64 to 71 there was a 5.2-mm Hg increase in systolic BP for every 1-kg decrease in birth weight. Although the LBW-hypertension hypothesis has been questioned by many and has yet to be rigorously evaluated in populations of African ancestry, it provides a unifying explanation for the increased salt sensitivity, severity of hypertension, and proclivity for the development of ESRD seen in this population.

Asians, Pacific Islanders, and Native Americans

Asians/Pacific Islanders are reported to have a similar or slightly higher level of BP and prevalence of hypertension.⁴⁶ Salt reduction in Asians/Pacific Islanders produces similar BP reduction as in black populations.⁴⁷ Although the data are extremely limited, the prevalence of hypertension in Native Americans appears to be similar to that in the general population. As in other populations, a higher incidence of hypertension is associated with obesity, older age, and diabetes.

Evaluation of Hypertension (see also Chapter 43)

True population-based surveys of the epidemiology of secondary causes of hypertension are not available. Despite the reported higher rates of salt sensitivity and responsiveness to BP reduction with diuretic therapy suggesting a volume overload–associated form of hypertension, particularly in black American cohorts, a racial difference in the prevalence of hyperaldosteronism has not been shown.^{48,49} Sleep-disordered breathing has been reported to be more common in black Americans, and the difference appears to be greatest at early ages (see Chapter 75).^{50,51} However, except for hypertension associated with renal disease and a higher incidence of sleep apnea, there is currently little evidence of significant racial or ethnic differences in the incidence or prevalence of secondary hypertension. Because the major factors (i.e., early age at onset, severity of hypertension, and resistance to therapy) triggering a search for secondary hypertension occur more commonly in black Americans with essential hypertension, evaluations for secondary hypertension based on these triggers are more likely to confirm essential hypertension in this subgroup. However, this should not discourage evaluation for secondary causes.

Racial/Ethnic Differences in the Treatment of Hypertension (see also Chapters 44 and 44G)

Goal Blood Pressure

The optimal BP for achieving maximal reduction in hypertensive complications has not been established, even in nonminority hypertensive populations. Randomized controlled clinical outcome trials in older (mostly nonminority) populations have documented the benefit of treatment to a systolic BP lower than 150 mm Hg versus a higher target.⁵²⁻⁵⁴ Several clinical outcome trials have also documented the lack of significant benefit of treatment to systolic BP targets lower than 120 mm Hg versus targets lower than 140 mm Hg in diabetic hypertensive patients or mean arterial pressure equivalent to 125/75 versus 140/90 in patients with chronic kidney disease (CKD).⁵⁵⁻⁵⁷ Only two small and underpowered randomized controlled outcome trials in older (age >60) Japanese hypertensive patients that compared systolic BP targets between 140 and 160 mm Hg are available.^{58,59} Thus recommendations for BP targets lower than 140/90 mm Hg remain based on expert opinion level of evidence. The higher risk for complications in black American hypertensive patients led the consensus panel established by the International Society of Hypertension in Blacks to recommend a lower BP goal (<135/85 mm Hg) in black Americans with uncomplicated hypertension and a goal of lower than 130/80 mm Hg in those with other risk factors for CVD or with clinical or subclinical target organ damage. However, there is little evidence that the lower BP targets in black Americans or other racial/ethnic subgroups result in better outcomes.⁶⁰ Studies such as the original Veterans Administration Cooperative Trials and the Hypertension Detection and Follow-up Program contained ample numbers of black hypertensive Americans and make a goal of lower than 140/90 mm Hg a very reasonable target in this population.

Treatment Strategies in Minorities (see also Chapter 44)

Lifestyle Strategies

As in the general population, lifestyle modification is recommended for all members of ethnic minority groups who have elevated BP. Calorie reduction is especially important in the black American, many Hispanic, and other minority populations with a high prevalence of obesity. Physical inactivity is also a particular problem in minorities; approximately half of black American adults (44% of men, 55% of women) report no participation in any leisure-time activity.³⁶ Reductions in dietary salt and improvements in diet quality (i.e., the DASH [Dietary Approaches to Stop Hypertension] diet) are also important in these populations. Recent guidelines from the U.S. Food and Drug Administration and the American Heart Association recommend more aggressive salt restriction (<1500 mEq/day), especially in black hypertensive individuals.

Drug Therapy (see also Chapter 44)

In most cases, drug selection for the treatment of hypertension in ethnic minorities is similar to that in the general population of hypertensives. The best evidence from clinical trials is that in the absence of specific indications (i.e., heart failure [HF], CKD, or CHD), it is the ability of the regimen to lower BP that is the major factor determining the effect of these agents on BP-related clinical outcomes in all racial/ethnic groups. In addition, most patients will require multiple agents to achieve their BP target. Almost all national guidelines, including those from the countries of origin for most minorities, have recommended initiating antihypertensive drug therapy with either a thiazide diuretic, angiotensin-converting enzyme (ACE) inhibitor, angiotensin receptor blocker (ARB), or calcium channel blocker (CCB) based on clinical outcome trial data documenting a reduction in clinical outcomes. In addition to ALLHAT (Antihypertensive and Lipid Lowering to Prevent Heart Attack Trial) and INVEST (INternational VErapamil SR Trandolapril Study), which contained a considerable number of Hispanics, significant numbers of Asians/Pacific

Islanders were included in several trials evaluating CCBs and RAS inhibitors.⁶¹⁻⁶³ Although surveys of Hispanics report lower rates of BP control, this group appeared to achieve higher rates of BP control than did non-Hispanic cohorts in both ALLHAT and INVEST.^{47,64}

There are several important racial/ethnic differences in response to some classes of antihypertensive drugs, and for this reason race/ethnicity should play a role in the selection of antihypertensive drugs. A variety of studies have shown that although BP-lowering efficacy is similar across population subgroups for most antihypertensive classes, black American patients respond better to diuretics and CCBs than to drugs that block the RAS (i.e., ACE inhibitors, ARBs, renin inhibitors, and beta blockers).³⁶ This racial difference is eliminated when these agents are combined with diuretics or CCBs, thus suggesting that the latter two classes should be preferred initial agents in this population. Abundant outcome data from randomized controlled trials with significant numbers of hypertensive black American subjects have demonstrated benefit of multidrug regimens that include a diuretic. ALLHAT enrolled more than 15,100 blacks (36%) and 8300 Hispanics (19%).⁶⁵ It compared treatment initiated with the ACE inhibitor lisinopril, the alpha blocker doxazosin, and the CCB amlodipine with treatment initiated with the thiazide-type diuretic chlorthalidone in black, Afro-Caribbean, and Hispanic populations. Neither of the newer classes were more effective than the diuretic arm in reducing any prespecified cardiovascular, renal, or stroke outcome in either population subgroup in ALLHAT.

Even though the primary coronary outcome in ALLHAT did not differ with respect to treatment assignment, there were significant differences in major secondary outcome rates by treatment group that were exaggerated in ALLHAT participants of African ancestry. Among those of African ancestry in ALLHAT, both ACE inhibitor and alpha blocker treatment assignment was associated with a significant increase in stroke, HF, and the combined CVD outcome when compared with assignment to diuretic treatment.⁶⁶ Adjustment for BP achieved failed to account for the racial differences in response to treatment. ACE inhibitor-based treatment was shown to be more effective in slowing the progression of kidney disease (mean rate of decline in the glomerular filtration rate [GFR] and the composite of ESRD, death, or 50% decline in GFR) than was amlodipine- and metoprolol-based treatment.⁶⁶ Diuretics are usually necessary for BP control in hypertensive patients with CKD; the ACE inhibitor was not more effective than the diuretic chlorthalidone in preventing negative renal outcomes in black Americans in ALLHAT.⁶⁶ In addition to racial/ethnic differences in BP-lowering and CVD outcomes, there are

also clinically important differences in the adverse effects of antihypertensive drugs. ALLHAT and other studies,⁶⁵ as well as some surveys of Asians, report a threefold to fourfold higher risk for angioedema and cough attributed to ACE inhibitors in black and Asian Americans than in white Americans.^{65,66} However, the LIFE (Losartan Intervention for Endpoint Reduction) trial provided no evidence that treatment with ARBs provides an advantage in black American hypertensive patients over diuretics, CCBs, or ARBs.

HEART FAILURE

Heart Failure in Black Americans

Epidemiology, Cause, and Clinical Features

The burden of HF is higher in black Americans than in any other U.S. ethnic or racial group, both in incidence and in prevalence.⁶⁷ The relative incidence of HF in black Americans is 50% higher than that in the general population, and the rate of hospitalization for HF in black Americans is also higher. When hospitalized for HF, black American patients have more risk factors such as diabetes and hypertension, which may be poorly controlled. The registry of the SOLVD (Studies on Left Ventricular Dysfunction) trial demonstrated that the cause of HF in black Americans was more commonly hypertension, in contrast to whites, in whom the strongest risk factor was coronary artery disease.⁶⁸ Recent data from the CARDIA investigations⁶⁹ have highlighted the magnitude of the dissimilarity between blacks and whites in the onset of HF. Young black adults are much more likely to be hypertensive, with a baseline incidence rate of almost 33%; more than 60% of those affected are either untreated or not treated to goal BP reductions. Even after enrollment in the CARDIA study for 10 years, the number untreated or not treated to goal remained at almost 50%, a prominent portrayal of disparate care. In this group of at-risk individuals, the subsequent development of HF at an early age is almost 20-fold greater than in whites (Fig. 2-3).⁶⁹ From a public health perspective these findings are extremely important and suggest the need for early detection and treatment to goal BP in young black adults as a strategy to prevent HF. As a case in point, rates of HF-related hospitalization in Medicare beneficiaries dropped substantially between the years 1998 to 2008. However, black American men had the smallest drop in rates when compared with white beneficiaries.⁷⁰ Although black Americans are hospitalized more frequently for HF, several studies have shown that in-hospital mortality, as well as 1-year mortality, is lower.⁷¹⁻⁷³ In Medicare beneficiaries, blacks have slightly better 1-year mortality.⁷⁴ Other studies have identified a higher 5-year case fatality rate in black than in white Americans.

Response to Therapy

Black Americans, as well as Hispanics, have been underrepresented in clinical trials of HF, particularly early ACE inhibitors studies. With small numbers of black Americans in the U.S. studies and none in European studies, only post hoc analyses can be done to extrapolate the results to sparse racial/ethnic groups. Black American representation in U.S.-based trials has been higher than that in multinational trials, but except for the Vasodilator Heart Failure Trials, which were performed in all-male Veterans Administration medical centers, black American representation in clinical trials is still lower than their estimated 25% to 30% representation of all HF patients in the United States. In the V-HeFT II trial, which compared enalapril with the vasodilator combination of hydralazine and isosorbide dinitrate, although the overall results of the trial favored

FIGURE 2-3 Role of hypertension in the development of HF in black Americans. In the CARDIA study, note the striking association of hypertension identified as a young adult with the subsequent development of HF and the significant variance in risk for the eventual development of HF in blacks versus whites. (From Bibbins-Domingo K, Pletcher MJ, Lin F, et al: Racial differences in incident heart failure among young adults. *N Engl J Med* 360:1179, 2009.)

FIGURE 2-4 Primary results from the African American Heart Failure Trial demonstrating a 40% survival advantage for blacks receiving isosorbide dinitrate (ISDN)-hydralazine (HYD) plus standard medical therapy versus placebo plus standard medical therapy. (From Taylor AL, Zeishe S, Yancy CW, et al: Combination of isosorbide dinitrate and hydralazine in blacks with heart failure. *N Engl J Med* 351:2049, 2004.)

enalapril, in post hoc analysis by racial groups there was a differential effect of the ACE inhibitor—it had greater benefit in white patients, whereas vasodilators had greater benefit in black patients.^{75,76} The contemporary A-HeFT trial confirmed the significant mortality advantage of combined isosorbide dinitrate and hydralazine added to neurohormonal antagonism in blacks (Fig. 2-4; see Chapter 25).⁷⁷ The black American response to beta blockers for HF has been somewhat contradictory: a post hoc analysis of the U.S. carvedilol studies suggested a similar benefit in reducing hospitalization rates across all races; however, numbers of black Americans were very small. In contrast, a real-world population in a large health care system showed a 40% to 50% lesser benefit in the black American patients with HF who were taking beta blockers. This difference remained in effect even when adjusting for the use of evidenced-based beta blockers.⁷⁸

Current HF guidelines have generalized recommendations to include all population subgroups while recognizing the limitations of this approach. In contrast to the greater uncertainty in the treatment effect of ACE inhibitors and beta blockers in black Americans, significant effects of the combination of isosorbide dinitrate and hydralazine on mortality and hospitalization were demonstrated in the A-HeFT trial.⁷⁷ Current guidelines give high priority to the use of this combination in addition to ACE inhibitors and beta blockers in black American patients with persistent symptoms of HF. However, in programs in which there have been consistent efforts to improve care, black Americans enjoy the same benefits from evidenced-based care as other races do.⁷⁹

Heart Failure in Hispanics

Epidemiology, Etiology, and Clinical Features

Data on the incidence of HF in Hispanics have not been abundant, which may be multifactorial, including poor data capture under ethnicity classification and poor enrollment of Hispanics in registries. In the MESA cohort of 6814 individuals (21.9% Hispanics) with a mean age of 61.3 years, the incidence of HF in Hispanics was 3.5 per 1000 person-years as compared with 2.4 per 1000 person-years in non-Hispanic whites and 4.6 per 1000 person-years in non-Hispanic blacks.⁸⁰ Once controlled for hypertension and diabetes, there was no difference among the ethnic groups. Much of the data on the prevalence of HF in Hispanics comes from review of hospitalization rates in various communities. The American Heart Association's Get with the Guidelines database provides an opportunity to examine large groups of patients in more than 250 hospitals across the country.

From January 2005 through December 2008, Hispanics accounted for 6.0% of hospitalizations for HF.⁸¹ Hispanic patients were significantly younger than whites (63 versus 78 years) and had lower ejection fractions with more diabetes and hypertension. Notwithstanding these differences, Hispanic patients had lower in-hospital mortality than whites did. Care was equitable across all racial and ethnic groups. Quality care, however, may not be available to all Hispanic groups. Elderly Hispanic patients may have a higher rate of readmissions if admitted to Hispanic-serving hospitals versus hospitals that do not specifically serve Hispanics. This difference may be due to language preferences among older Hispanics, in whom English fluency may not be common.^{82,83} Hispanic patients admitted for acute decompensated HF also tend to be younger than white patients and have more renal insufficiency.⁸³ In a review of Medicare beneficiaries from 1990 to 2000, the prevalence of hospitalization for HF increased in all racial and ethnic groups and rose with increasing age. When compared with non-Hispanic whites, the likelihood of hospitalization for HF was 1.2 times higher in Hispanic beneficiaries. However, rates of in-hospital mortality were lower in both blacks and Hispanics than in whites. Hispanics were also more likely than whites to be discharged home.⁸⁴ With the growing number of older Hispanics, the prevalence of HF with preserved ejection fraction (HFpEF) should be considered. From Get with the Guidelines from 2005 to 2010, 46% of the Hispanics had a diagnosis of HFpEF and 54% had HF with a reduced ejection fraction (HFrEF) as compared with 55% and 45% of non-Hispanic whites, respectively. Multivariate analysis showed a significantly higher risk for mortality in Hispanics with HFpEF than in non-Hispanic whites, but not in those with HFrEF. Quality of care and performance measures did not vary by ethnicity, once again providing evidence of lack of disparity in care in centers in which quality outcome programs exist.

Response to Therapy

Little is known about the differential effects of medications on Hispanics given the small numbers of patients enrolled in the randomized clinical trials. Disparities in device therapy have been noted, and fewer cardioverter-defibrillators are implanted in Hispanics, blacks, and women who would otherwise be eligible patients. There is, however, no reason to withhold evidence-based medical therapy and device therapy.

SUMMARY

The risk for heart disease and stroke affects all ethnic and racial populations in the United States. However, there are important differences regarding risk for CVD and outcomes in different populations in the United States. Although a complete explanation for these differential outcomes is not apparent at this time, it probably reflects a complex interplay of cultural, political, physiologic, and genetic variances among the different populations. Because of the untoward consequences of heart disease, it is imperative that the practice of cardiovascular medicine address the nuanced risk profiles and different manifestations of disease within varied populations.

Ethical issues are inherent in medicine, and cardiology is no exception. The breadth of cardiovascular disease means that almost every ethical challenge in medicine arises. These disorders affect all age groups, range from highly acute to chronic, entail variable prognoses, and have a wide range of impact on patients' lives. Moreover, cardiac disease accounts for significant health care cost and public health burden. Although many ethical issues that cardiologists face are not unique to cardiology, certain issues have particular salience, and special considerations are raised by cardiac disease and its treatment.

This chapter considers five broad categories of ethical issues: (1) informed consent and shared decision making; (2) end-of-life care; (3) ethics of clinical research; (4) resource allocation; and (5) conflict of interest (COI). Within each category, issues of particular or unique relevance in cardiology are highlighted.

INFORMED CONSENT AND SHARED DECISION MAKING

Working with patients to make decisions that reflect their values and goals is essential to the physician-patient relationship. This commitment has firm ethical underpinnings in the principles of respect for autonomy and beneficence. In contrast with paternalistic conceptions that might have prevailed in the past, it is now accepted that patients should be free from unwanted treatment and able to choose treatments that match their values and interests. Of importance, the courts have also recognized patients' rights to make medical decisions, and recent policy and research efforts have elevated patient-centeredness and shared decision making as national priorities.

A legal and ethical standard for most procedures and many interventions, informed consent is designed to ensure that patients understand a proposed treatment, appreciate the risks, benefits, and alternatives, and voluntarily agree to the treatment. The four key elements of informed consent are (1) assessment of the patient's decision-making capacity, (2) disclosure of relevant information, (3) assessment of the patient's understanding of the information, and (4) ensuring that the patient's decision is voluntary and made free from coercion or undue influence.^{1,2} Although signed informed consent forms attesting that these steps have occurred are the norm in the United States, such forms are primarily a token of the process that facilitates documentation. It is ultimately the disclosure, understanding, and consent that are the key ethical values to be realized.

Signed informed consent typically is sought for discrete decisions about procedures or diagnostic tests involving appreciable risk. As a rule, formal consent is not obtained for medical therapy, even for medicines and interventions such as warfarin or antiarrhythmic therapy that carry important risks. This difference is driven more by convention and practicality than by real ethical distinctions. Developing and implementing processes that inform and involve patients in these decisions and result in treatments that match their goals are clear ethical responsibilities.

A growing appreciation has emerged for the importance of shared decision making in clinical medicine and of active research aimed at identifying deficiencies and improving practices of shared

decision making.³ Innovative strategies have included decision aids that range from interactive modules to simple and individualized forms.⁴ Numerous practical barriers to effective shared decision making are recognized. A generic barrier is the difficulty of communicating and having patients understand risk, benefit, and uncertainty. Probabilistic reasoning is challenging to communicate, and estimates of individual risk and benefit are often unavailable or unknown. Efforts to improve risk communication using pictograms depicting absolute risk and individualizing risk estimates offer promise.^{5,6} Decision aids incorporating these tools have increased patient knowledge of relevant procedural risks and benefits and represent progress toward evidence-based approaches for fulfilling these ethical commitments.⁴

Shared decision making also requires successfully eliciting patients' values and priorities. This can be challenging in the absence of long-term relationships and in the context of logistical and financial pressures that promote "efficiency." Additionally, because patients may not understand exactly what is at stake in many situations, helping patients to articulate their goals of care is essential. Many decision aids explicitly incorporate values clarification elements that help to address this barrier.

Two common decisions in cardiology pose special and illustrative challenges regarding shared decision making. The first involves treatment for chronic stable angina. Therapies vary significantly, ranging from coronary artery bypass grafting (CABG) to percutaneous coronary interventions (PCIs) to medical treatment—yet the principal goal often is symptom control and not prolongation of survival. These decisions should be guided by patients' goals, but available data suggest that patient involvement is often minimal.⁷ One reason for this lack of involvement is the "stuttering" or staggered decision-making process that characterizes these situations. In the process of evaluating and treating angina, there are numerous treatment and diagnostic options and multiple points at which the patient may be involved, from decisions regarding an initial stress test to those about catheterization and intervention. The ultimate decision about intervention, however, often is made while the patient is sedated and at times by interventionalists with incomplete knowledge of the patient's priorities or overall clinical picture. Properly carving out time for discussion, figuring out ways to communicate risk and downstream decisions early in the process, and adequately incorporating patients' goals into these decisions are challenging but important tasks. Developing and using standardized decision aids for such common interventions could be helpful.

A different challenge surrounds use of implantable cardioverter-defibrillators (ICDs) for primary prophylaxis. Communicating the preventive nature of the therapy, the absence of symptomatic benefit, and the long- and short-term risks can be difficult. Proper discussion about ICD implantation also should be intertwined with discussions regarding quality of life and goals of care and should address options for deactivation. Recent studies have found significant variability in these discussions. Cardiologists often stress benefits and guideline-based indications for therapy. Patients often overestimate benefits and are uncertain about risks and quality-of-life implications of ICD therapy.^{8,9} Of interest, only 37% of physician respondents in one survey thought that patient preferences mattered "a great deal," and

12% thought they mattered “very little” or “not at all” in this context.¹⁰ If physicians do not think patients’ preferences matter, it is no surprise that efforts to engage patients in decision making are not more common. ICD decisions, however, are preference-sensitive. Despite a clear mortality benefit in properly selected patients, these decisions involve trade-offs between living with heart failure and risk of sudden death, some risk of complications, and a need for regular monitoring.¹¹

Coronary artery disease (CAD) treatment and ICD decisions illustrate the importance and difficulty of shared decision making. In the CAD case, patients’ values and involvement are important because of the lack of mortality difference or obvious superiority of different treatment approaches and real qualitative differences including risks. Practical barriers to implementing shared decision making, as noted, complicate involvement. In the ICD case, medical benefits and risks are clear. However, they can be difficult to communicate, “lived” risks and benefits can only be ascertained through individual patients’ values and goals, and many physicians appear reluctant to engage patients in these decisions.

END-OF-LIFE CARE

All medical fields face ethical challenges regarding care at the end of life. These challenges go back to Hippocrates and the dawn of medicine. Cardiovascular disease remains the leading cause of death in the United States, accounting for an estimated 811,940 deaths—almost a third of all deaths—in 2008.¹² Some cases are acute, but most involve a chronic phase that permits end-of-life discussions. Cardiologists must be prepared to face a wide variety of end-of-life challenges. They must regularly work with patients and families to make decisions about when to pursue aggressive treatment in the face of high-mortality conditions, when to withdraw support, and when to initiate do not resuscitate (DNR) orders.

These challenges are ubiquitous and their ethical and legal underpinnings generally well established. However, cardiologists face a special set of challenges in caring for patients with advanced heart failure and those who rely on medical devices. These challenges are growing with increasing prevalence of heart failure and rapid expansion and improvement in mechanical circulatory support.¹³

Addressing the needs of today’s advanced heart failure patient is increasingly complex, as medical and device therapies improve while mortality and morbidity remain high. As illness progresses, patients and physicians both have to prepare for the worst while hoping for the best, particularly when patients are candidates for advanced therapy with transplantation or placement of a ventricular assist device (VAD). American College of Cardiology/American Heart Association (ACC/AHA) guidelines specifically recognize the need for advance care planning and palliative care involvement in advanced heart failure, and there has been support for early involvement and integration of palliative care specialists into VAD/transplant evaluations.¹⁴ This development is due to increasing recognition that palliative care specialists offer more than hospice care and that a model of “preparedness planning” incorporating advance care discussions and goals clarification can facilitate care that coheres with patients’ values. This model can be particularly helpful when sudden events or changes in clinical status arise and is entirely consistent with aggressive treatment plans.¹⁵ Further research will help to optimize timing of discussions, clarify roles of palliative care specialists and cardiologists, and improve communication.

Deactivation of implantable devices is an important component of end-of-life care. Guidelines from the Heart Rhythm Society and European Heart Rhythm Association explicitly state that implantable defibrillators and pacemakers in particular can, and should, be deactivated when patients so choose.^{16,17} These positions follow long-established ethical and legal analysis. Respecting patients’ autonomy entails allowing them to be free from unwanted medical interventions, even life-prolonging interventions. Again, well-established ethical and legal reasoning demonstrate that withdrawing device support or treatment that is no longer desired by the patient, but may

prolong life, is not ethically different from not implanting the device in the first place. The lethal process is the underlying disease state and not the physician’s action. This is the basis on which these activities are both ethically and legally distinguished from physician-assisted suicide (PAS) or active euthanasia. It is widely accepted as justifying the withdrawal of such therapies as mechanical ventilation, artificial nutrition and hydration, and dialysis. Despite relative consensus in the scholarly literature, the process of deactivation still raises concerns on the part of many practitioners.¹⁸

The greatest controversy has focused not on ICDs but rather on pacemakers (in pacemaker-dependent patients) and VADs for three principal reasons. First, deactivation of continuously “active” devices typically results in death in the very short term. Second, these devices, once implanted, replace a normal function of the heart and do not themselves generally cause discomfort or harm. Third, dependency on pacemakers in particular is sometimes intentionally induced in attempts to control tachyarrhythmia.^{19,20} Consequently, some have argued that deactivating these devices, particularly if a patient is otherwise not acutely ill, represents a form of PAS or active euthanasia. Indeed, some European countries do not officially allow pacemaker deactivation in pacemaker-dependent patients.¹⁷

The emotional difficulties related to these decisions are obvious. However, no ethically or legally defensible basis exists for refusing to acknowledge a patient’s informed, authentic request to deactivate any cardiac device, regardless of the immediacy of death as a consequence. A long legal history favors honoring such requests, and physicians routinely withdraw other forms of treatment, including dialysis and mechanical ventilation, with similar features. The right to be free from unwanted intervention is clearly conceptually distinct from PAS and euthanasia. As recognized in available guidance documents, providers uncomfortable with a deactivation procedure may refuse to perform it but should refer the patient to a willing provider if that is indeed the patient’s wish.

Important practical challenges remain. All published data suggest that the option of ICD deactivation in particular is inadequately communicated to patients both at the time of implantation and subsequently.¹⁸ This shortcoming probably reflects discomfort with deactivation and absence of training regarding these discussions. Patients should be made aware of deactivation options, particularly in the face of advancing illness or receipt of shocks, whether appropriate or inappropriate.

ETHICS OF CLINICAL RESEARCH

Cardiology has been revolutionized by clinical research, and evidence-based therapy undergirds much of current care. Nevertheless, outcomes are still unacceptable for many conditions, and effective therapies have not been identified for many major causes of morbidity and death. Therapies with novel mechanisms and targets continue to emerge, and further study of existing therapies lacking an adequate evidence base is needed. Clinical research is as important as ever; addressing its ethical challenges also is critical.

The overarching goal of research ethics and human subjects protections is to minimize exploitation.²¹ In clinical medicine, a primary focus is on promoting the individual patient’s best interests; in research, the primary focus is on developing scientific knowledge. This shift creates an opportunity for exploitation of research subjects; they are used to advance knowledge that will benefit others in society.

Research that successfully avoids exploitation is guided by eight ethical principles: (1) collaborative partnership with relevant community stakeholders; (2) social value; (3) scientific validity; (4) fair participant selection; (5) favorable risk-benefit ratio accounting for risks and benefits to both subjects and society; (6) independent review; (7) informed consent when possible; and (8) respect for participants (Table 3-1).²²

Two critical components of this framework are that informed consent alone is never sufficient to make a study ethical and that basic elements of study design have fundamental ethical implications.

TABLE 3-1 Eight Principles of Ethical Clinical Research*

ETHICAL PRINCIPLE	DEFINITION/BENCHMARK
Collaborative partnership	Investigators identify and involve relevant stakeholders in planning and conduct of research.
Social value	Research addresses a clinical need and may lead to meaningful improvements in practice.
Scientific validity	Study design and endpoints are chosen in order to ensure that the clinical question is answered.
Fair participant selection	Participants are selected on the basis of scientific considerations and in order to maximize benefit and minimize risks.
Favorable risk-benefit ratio	Potential physical, psychological, social, and economic risks to participants are minimized and justified by potential for benefit to participants and society.
Independent review	Research is reviewed by an independent body with appropriate human subjects protections knowledge, scientific expertise, and knowledge of participants.
Informed consent	Recruitment materials and strategies are appropriately designed to optimize potential participant's understanding of important study details and ensure the absence of undue influence or coercion.
Respect for participants	Procedures are in place to recognize participants' contribution by ensuring dissemination of results, monitoring the well-being of participants, and protecting their confidentiality.

*Modified from Emanuel EJ, Wendler D, Grady C, et al. An ethical framework for biomedical research. In Emanuel EJ, Grady C, Crouch RA, et al (eds): *The Oxford Textbook of Clinical Research Ethics*. New York, Oxford University Press, 2008, pp 123-135.

Studies that are inadequately powered to detect key endpoints do not have adequately defined inclusion or exclusion criteria, or do not reflect the population in which a therapy would be delivered are unethical. They lack social value, fail to respect participants' contributions, and squander scarce research resources.²³

Perhaps the most widely known principle of ethical study design in the context of randomized trials is the concept of *clinical equipoise*. Investigators and individual clinicians are rarely completely ambivalent about the benefits of different "arms" in a study. Clinical equipoise requires legitimate uncertainty within the field of experts regarding which of two or more comparison groups in a trial is superior.²⁴ Although the specific concept of equipoise as a standard has been criticized, legitimate uncertainty by the group of experts about treatment superiority is essential for a trial to be ethical in most circumstances.^{25,26} Determining adequate uncertainty, however, can be challenging. Varying levels are inevitable, and no standards exist for assessing whether the body of experts is in "enough doubt" to allow randomization. In some trials, for example, trials comparing PCI or CABG and medical therapy for CAD, qualitative differences between treatments can complicate these comparisons.

Just as it can be difficult to determine whether legitimate uncertainty is present at a study's outset, the job of data and safety monitoring boards (DSMBs) to determine whether equipoise has been sufficiently disturbed during the course of a trial to warrant stoppage due to futility, benefit, or harm can be difficult. Early stoppage is often controversial, in part because it tends to result in overestimated benefit, may compromise collection of clinically important secondary endpoints, and can leave substantial clinical uncertainty about long-term risks and benefits.^{27,28} Continued randomization in the presence of inadequate uncertainty is, however, unethical. Controversies

in cardiology regarding early stoppage of trials of perioperative beta blockade, fractional flow reserve (FFR)-guided revascularization, and lipid-lowering therapy have all illustrated the difficulties and impact of these decisions.^{27,29,30}

The ethical requirement for informed consent also can pose significant challenges in cardiac research, particularly in acute illness. Clinical treatment of conditions such as acute myocardial infarction (AMI), cardiac arrest, or acute decompensated heart failure often takes place under circumstances in which consent is either impossible or highly problematic. Even when patients are asked for consent, their true understanding and level of engagement are frequently minimal because of their illness.

Federal regulations allow an exception from informed consent (EFIC) for research in emergency settings where consent is not possible within an appropriate timeframe. Although still controversial to some extent, it is generally recognized that EFIC research in emergency settings can be ethical.³¹ The EFIC regulations have appropriately stringent requirements, including that: (1) informed consent must not be feasible in the timeframe within which enrollment must occur; (2) the condition under study must be life-threatening; (3) current treatment must be unsatisfactory or unproved; (4) the study must offer some prospect of direct benefit; (5) risks and benefits must be reasonable in light of the condition; (6) the trial could not be carried out in a population that can provide consent; and (7) investigators must conduct community consultation and public disclosure.³² These regulations are designed to maximize the extent to which research participation coheres with critically ill patients' overriding interest in survival with maximal cognitive functioning.

The community consultation requirement has been particularly controversial, in part because it is not required for other types of research and in part because its primary purposes remain somewhat ambiguous. Moreover, federal guidance only specifies very broad metrics by which community consultation can be assessed, established criteria for interpreting community feedback are lacking, and consultation efforts may take many different forms and involve considerable expense.^{33,34}

EFIC studies represent a small proportion of cardiology trials, principally those dealing with cardiac arrest and cardiogenic shock. However, many acute cardiac trials involve significant barriers to consent. It is well documented, for example, that consent is suboptimal in STEMI trials.³⁵ This is not surprising in view of the urgency of this clinical situation, the time frame within which treatment must be given, and the presence of significant symptoms in affected patients. Moreover, patients' surrogates are often under the same time pressures and in significant distress. Clear regulatory provisions to allow adaptations to the consent process in these circumstances are lacking, as is evidence on how best to involve patients in decisions. Of interest, the GISSI and ISIS trials of thrombolytic therapy in the 1980s explicitly did not ask patients or surrogates for consent on the basis that consent was thought to be an unjustifiable and unproductive burden in the context of AMI.³⁶ Although this approach probably would not be accepted today, ascertaining how to involve patients meaningfully while recognizing unavoidable barriers to consent that are intrinsic to these clinical circumstances is an important priority.³⁵

A final research ethics issue that will grow in an era of health system reform is the integration of research into clinical practice.³⁷ With continued migration to electronic record systems and increasing emphasis on comparative effectiveness and "real world" research, the traditional separation between research and clinical medicine may dissolve. This development has important advantages, particularly in addressing declining and sluggish research enrollment, but it poses challenges. Comparative effectiveness studies, for example, that examine commonly used treatments may ideally be performed on a large scale within health systems. The ethical standards for institutional review board (IRB) review and informed consent for these trials may plausibly differ from trials involving new agents.³⁸ Similarly, the paradigm of partnerships between payers such as the Centers for Medicare & Medicaid Services (CMS) or other large insurers with the National Institutes of Health (NIH) and other research

fundlers may create circumstances where coverage of innovative treatment is contingent upon trial participation.^{39,40} These programs, as well as U.S. Food and Drug Administration (FDA) programs to facilitate accelerated review and approval in the context of treatment for serious or life-threatening conditions, attempt to balance patients' need for access to innovative therapy with the need for rigorous evaluation before these therapies are distributed for clinical use.⁴¹ These potentially productive paths for improving health care blur distinctions between research and clinical care, involve clinicians in research activities in new ways, and require further work to define adequate protections.

RESOURCE ALLOCATION

Some of the most prevalent and troublesome challenges in cardiology relate to resource allocation. Cardiology care is expensive, numerous high-technology, high-cost interventions are available and effective, and patient demand and expectations (whether informed or not) are high. At the same time, the need for judicious use of resources is increasingly recognized in an era of rising costs and health care system change. What is often underrecognized is the underlying ethical nature of these decisions. Data regarding relative costs and benefits of particular treatments inform decisions, but decisions ultimately rely on ethical frameworks for valuing specific outcomes and costs.

Significant variability has been demonstrated in the use of many cardiac procedures. Although some variability is appropriate and reflects acceptable differences in clinical judgment, excessive geographic variability and use in cases that do not comply with guidelines, as has been demonstrated in use of PCI for stable coronary disease, for example, raises concerns.⁴² The principal mechanism by which cardiology has tackled challenges of resource allocation and over-use has been through development of *appropriate use criteria* (AUC). AUCs represent an important step forward in the attempt to ensure that care is being provided in a way that is evidence-based and appropriate. AUCs have been used to examine practice patterns and to facilitate estimates of the magnitude of inappropriate use, for example, of PCI and implantable devices.⁴³ Although these estimates have been controversial and are, of course, inexact to some degree, AUCs have facilitated an important shift toward standardization and reduction of inappropriate care.

AUCs generally are directed at identifying use of treatment or diagnostic modalities for which there are data to support clinical benefit. Many difficult decisions, however, require fundamentally ethical judgments about what constitutes value. One obvious example is selection of patients for transcatheter aortic valve replacement (TAVR). TAVR has revolutionized treatment of severe aortic stenosis in patients who are not good surgical candidates, most of whom are of advanced age and often have limited life expectancy and multiple comorbid conditions. Particularly because these procedures are paid for predominantly by Medicare, use of TAVR has significant implications for U.S. health care costs at a time of increasing awareness of the need to constrain costs. Significant attention has thus been focused on evaluating cost-effectiveness of this therapy. Published analyses have produced variable results, and estimates will surely change as experience with this therapy evolves and in the context of different patient populations.^{44,45} What cannot be ignored, however, is that decisions regarding use must balance patients' comorbidities, likelihood of benefit, and life expectancy. The relevance of age is more controversial. Striking these balances will be inevitably difficult but is an essential ethical task.

Overt resource allocation decisions are part of everyday practice in advanced heart failure management. Because of the fixed supply of transplantable organs, the interests of the population of potentially eligible and eligible transplant candidates must be balanced. Rationing is unavoidable when giving an organ to one patient means that another may die. These decisions have become more commonplace as heart failure prevalence rises and the supply of transplantable organs remains fixed. Screening processes designed to identify those

likely to have the best outcomes are critical, although challenges remain regarding how to assess and weigh various factors. In particular, assessing the relevance of variations in social and economic support, age, and comorbidity often complicates transplant eligibility decisions, and there is a need for continued discussion along with additional data on how best to weigh and evaluate these factors in a way that ensures justice but appropriately favors good outcomes among recipients of a truly scarce resource.

The option of left ventricular assist device (LVAD) implantation for destination therapy or as a bridge to transplantation or transplant candidacy raises somewhat different resource allocation challenges. Although the supply of transplantable organs is absolutely fixed and the need for explicit rationing of organs overt, this is not the case with mechanical devices. There is no shortage of VADs; placing a VAD in one patient does not entail denying this therapy to another. Associated costs, however, are significant, and outcomes with VADs are highly variable because of requirements for complex aftercare and the potential for numerous devastating complications. Predictors of good outcomes are thus critical to consider, both for patients' interests and for wise use of resources. However, the "moral weight" of various risk factors in this context is less clear than in transplantation.⁴⁶ Particularly when VAD candidates have relative contraindications (be they social or medical) but will clearly die without mechanical support, it becomes essential to consider whether giving those patients a chance is "worth" the investment. Striking this balance requires continued research into predictors of outcomes, but as in the TAVR case, it also requires clinicians to confront, as practitioners in the field and as members of society, long-avoided questions regarding rationing and value in health care.

CONFLICT OF INTEREST

Addressing COI has been a priority in cardiology and across all of medicine.⁴⁷ As defined by the Institute of Medicine, COIs are "circumstances that create a risk that professional judgments or actions regarding a primary interest will be unduly influenced by a secondary interest."⁴⁸ The primary interest of cardiologists is to promote the well-being of their patients and, if they are engaged in research, to produce reliable and valid generalizable knowledge. Secondary interests may be securing grants, obtaining promotion, participating in departmental governance or professional societies, and securing income. Of importance, these secondary interests are not unethical. Indeed, many are laudatory. COIs arise because these secondary interests may compromise a professional's primary interest and judgment.

Of note, situations that create the *appearance* of conflict are not essentially different, at a practice or policy level, from situations in which true compromise of judgment actually occurs.⁴⁹ The central consideration in addressing and managing COI is to create contexts in which inappropriate influences are minimized and in which observers can feel confident that they know and can reliably trust professional judgments. The structure of different types of conflicts may vary, but the cornerstones of most attempts at addressing COI are three: (1) disclosure, (2) management and oversight, and (3) prohibition or conflict avoidance.

Powerful influences can affect at least five stages of clinical research (**Table 3-2**).⁵⁰ Interestingly, data suggest that industry sponsored research is highly methodologically rigorous, particularly at the design and patient enrollment stages.^{51,52} Where industry sponsorship has created the most significant COI problems is around dissemination of results. Here, studies have demonstrated marked tendencies toward publishing positive results, selective publication of studies, including infrequent publication of negative studies or the multiple publications of positive results, potential bias in interpretation of results, alteration of endpoints between design and publication, and failure to report results completely.⁵¹⁻⁵⁴ For example, major controversies surrounding the trials of COX-2 inhibitors rofecoxib and celecoxib involved selective reporting of data critical to assess these drugs' risks and benefits.⁵⁵⁻⁵⁷

TABLE 3-2 Stages of Clinical Research and Potential Conflict of Interest

STAGE OF RESEARCH	POTENTIAL AREAS OF CONFLICT
Study conception	Choice of primary study question may be driven by multiple potential interests.
Research design	Fundamental design elements (e.g., sample size, randomization scheme, choice of endpoints) differently advance competing interests (securing marketing indication versus clinical usefulness).
Subject recruitment	Biased selection or follow-up may compromise data integrity.
Data analysis	Choice of analytic methods or exploration (or absence of exploration) of alternative explanations can have heavy impact on findings.
Dissemination	Negative findings may not be submitted for publication or may be downplayed in reports. Positive results may be published multiple times.

In assessing and addressing COIs, an important point is that they are not all the same. Thus, it is essential to determine (1) the likelihood that a secondary interest might distort professional judgment and (2) the seriousness of harm that might result from a conflict.⁵⁸ Even if a conflict is likely to arise, fewer safeguards may be necessary if the seriousness of resulting harms is minimal. Conversely, serious harms, such as potential for disability or death—even if the likelihood of conflict is low—may necessitate more stringent safeguards.

The main safeguards to minimize the impact of conflicts of interest are three: (1) disclosure, (2) management, and (3) prohibition. Although disclosure may be necessary, it may not be sufficient in many cases. Disclosure often places responsibility for resolving the conflict on the least powerful member of a health team: the patient.⁵⁹ Although disclosure is a meaningful component of addressing COI in research, efforts to promote dissemination of patient-level data, for example, have the potential to mitigate conflicts in far more meaningful ways.⁶⁰

Within clinical practice, COI also is an inherent and pervasive concern. From interactions with drug representatives to basic reimbursement strategies, multiple interests are at stake in clinical medicine that compete with the primary goal of advancing patient care. Fee-for-service medicine, for example, explicitly incentivizes overtreatment. Capitated payment, on the other hand, incentivizes undertreatment. These tensions are unavoidable and must be balanced, are not mitigated by mere disclosure, and require solid data to facilitate evidence-based and rational approaches.

CONCLUSIONS

There is no shortage of ethical challenges in cardiology today, and many do not have easy answers. However, we can continue to make progress in addressing them. Deep conceptual questions may persist, but rigorous research can result in evidence-based approaches to ethical challenges in the same way that it can inform clinical decisions. Implementation and evaluation of decision aids to improve shared decision making and strategies to address COI, for example, can maximize desirable outcomes. Further research into communication regarding device implantation and into the costs and benefits of innovative therapies can better inform patients' and physicians' decisions. These challenges cannot be eliminated, but they can be addressed and our approaches improved.

Clinical decision making is central to all patient care activities. It involves making a diagnosis and selecting actions from among alternatives. Clinicians are continually faced with decisions, some that are made deliberately and others urgently. In most cases, these decisions must be made under conditions of uncertainty. Some decisions can be made in full partnership with patients; others must be made on behalf of patients. With today's growing array of diagnostic and therapeutic options and escalating health care costs, there is an emerging focus on decision making.

This chapter highlights key issues in clinical decision making in cardiology. The true breadth of the science of clinical decision making is enormous, spanning disciplines that include statistics, sociology, psychology, economics, and political science. The many issues that require consideration include hypothesis generation and refinement, use and interpretation of diagnostic tests, causal reasoning, diagnostic verification, therapeutic decision making, and cognitive tools and pitfalls.¹ This last category comprises heuristics, clinical prediction rules, and other tools. Despite the broad scope of this topic, clinicians should be familiar with a key set of concepts that can enhance their decision-making skills and promote the best interests of each patient.

DIAGNOSTIC DECISION MAKING: GENERAL CONSIDERATIONS

Making the correct diagnosis by using the least harmful and least costly approach is critical to the proper care of patients. Diagnoses can classify patients by their underlying pathophysiology, prognosis, and response to therapy. Delays in diagnosis, or an incorrect diagnosis, can have marked adverse consequences.

Many conceptual models underlie the way in which clinicians approach diagnosis. *Deductive inference* starts with a hypothesis that can be tested. Observations and test results can be assessed for their consistency with the hypothesis. *Inductive inference* starts with empiric observations and then develops an applicable hypothesis. Medical diagnosis is often based on inductive inference, asking the question "Given the patient's condition, what is the likelihood of different diseases?"

DIAGNOSTIC TESTING

Good decision making requires a thorough understanding of the strengths and limitations of each diagnostic test. Test characteristics convey information about the performance of a test and can be expressed in terms of sensitivity, specificity, likelihood ratio, and positive and negative predictive values. For clinicians to be able to incorporate diagnostic test results into clinical decision making, they should be familiar with the following definitions.

Sensitivity and Specificity

Sensitivity: among people who have the disease, the proportion with a positive test result (true positive)

Specificity: among people without the disease, the proportion with a negative test result (true negative)

Knowledge of these test characteristics can assist in the interpretation of results and their implications for the patient. High-sensitivity tests have low false-negative rates. A test with a high sensitivity will give a positive result in almost all persons with the condition being tested. Thus a negative result on a test with high sensitivity makes the diagnosis highly unlikely, essentially ruling out the condition. Conversely, a test with high specificity will have a low false-positive rate. A test with a high specificity will give a negative result in virtually all persons without the condition being tested.

Studies that define the sensitivity and specificity of a certain test may also be flawed, and clinicians should be alert to problems with these estimates. In high-quality studies, the diagnostic test should be compared with a gold standard that is measured independently. Stable estimates of test characteristics require large study populations. Nevertheless, issues of generalizability arise, because published test characteristics tend to reflect the performance of the test in excellent centers, with experienced clinicians using the most advanced technology.

The test characteristics, moreover, are not always an intrinsic feature of the test. Practitioner skill and patient factors may affect the performance of some tests. For example, it is difficult to assign a sensitivity and specificity to transthoracic echocardiography for the detection of a vegetation, because the performance of the test may vary with the skill of the technician, the quality of the equipment, and the acoustic windows and cooperation of the patient.² By contrast, computed tomography (CT) images tend not to vary by patient and therefore have a more consistent sensitivity and specificity. In considering the characteristics of a test that varies by patient, it is important to take into account circumstances of each clinical situation. The variation in interpretations, even with the same studies, also is often not appreciated. Repeated studies of angiography have demonstrated that clinical interpretations often do not agree with panel assessments or autopsy reports or simulated lesions.³

Predictive Values

Positive predictive value: among those with a positive test result, the proportion of people who have the disease

$$PPV = \text{sens} \times \text{prev} / [\text{sens} \times \text{prev} + (1 - \text{spec}) \times (1 - \text{prev})]$$

Negative predictive value: among those with a negative test result, the proportion of people who do not have the disease

$$NPV = \text{spec} \times (1 - \text{prev}) / [(1 - \text{spec}) \times \text{prev} + \text{spec} \times (1 - \text{prev})]$$

These values convey information about how the test result translates into the likelihood that a particular patient has the disease. The key insight about predictive values is that unlike sensitivity and

specificity, they are highly dependent on disease prevalence. If the prevalence is low, a positive highly specific test will still not yield a high likelihood of disease (i.e., the test has a low positive predictive value despite the exemplary test characteristic). The implication is that even with a test with high specificity, the screening of a low-risk population will still yield many false positives.

Example: A young woman comes to your office with a result of a positive exercise stress test as indicated by electrocardiographic changes but with good exercise tolerance. The test was ordered for atypical chest pain. She has no traditional risk factors for coronary artery disease, including family history, and wonders whether this test is likely to be an indication that she has heart disease. To make a point, pretend that her risk of disease is 1 in 1 million and that the stress test has a sensitivity and specificity of 75%; then for every 4 million women in her risk group, 4 have disease and 3 have a positive test result. Of the almost 4 million without disease, 1 million have a positive test result. Therefore, for every 1 million positive test results, only about 3 would represent a true positive. Even if the screening test had a sensitivity of 100% and specificity of 99%, then for every 10 million women screened, 10 have disease and 10 have a positive test result. Of the approximately 10 million without disease, 100,000 have a positive test result. Thus for every approximate 100,000 positive test results, only 9 would represent a true positive.

Bayes Theorem. The Bayes theorem expresses how the probability of disease should change with new information. The posterior, or post-test, probability is a function of the prior, or pre-test, probability (or disease prevalence) and the likelihood ratio. This theorem provides a way to revise estimates based on new information. In essence, it relates a conditional probability: the probability of A given B. Conceptually, it formalizes the incorporation of previously obtained information into the interpretation of new information. A test that does not change a prior belief may be unnecessary.

Likelihood Ratio

Likelihood ratio (LR): the ratio of the probability of a certain test result in people who have the disease to the probability in people who do not have the disease

$$LR+ = \text{sens}/(1 - \text{spec})$$

$$LR- = (1 - \text{sens})/\text{spec}$$

The post-test odds that a patient has the disease can be calculated with the LR: pre-test odds \times LR. An LR value of 1.0 does not modify the post-test probability, thus indicating a test that provides no useful information.

Defining Abnormal

Another important issue in the use of diagnostic tests is the definition of *normal*. By convention, test results are often characterized in a binary fashion (normal/abnormal), which is a translation from a continuous result. Ideally, test results are translated into quantitative post-test estimates. For example, noting that an exercise stress test result is abnormal is much less informative than providing an estimate that a patient has ischemic heart disease based on a result that takes into account the exercise time, the symptoms, the blood pressure response, and the type of electrocardiographic changes. Not all “positive” tests have the same meaning for a patient.

Considerations in Test Ordering

Decisions about test ordering are often difficult, because too few studies have compared alternative testing strategies for patients with a given set of signs and symptoms. A test can reduce uncertainty about a diagnosis and estimates of risk, but the key issue is whether patients undergoing the test have better outcomes than those who are not tested. In current practice, there is substantial variation in testing patterns that seem independent of the patient's characteristics.⁴

The construct of *number needed to treat* (NNT) also can apply to screening tests.⁵ The number needed to screen, which is defined as the number of people who need to be screened over a defined period to prevent an adverse event, takes into account the number of people tested to identify those with a specific condition that may be

amenable to a specific treatment strategy. The metric can convey how many must be tested for one individual to experience a benefit.

Example: A middle-aged man with hyperlipidemia is about to be started on statin therapy. You remember a recent article that identified a single-nucleotide polymorphism that predicts the risk of myopathy and can identify individuals with a risk of almost 20%. Then you realize that in the published study, of more than 8000 patients taking a statin only about 10 cases of myopathy, which were reversible, were attributable to this single-nucleotide polymorphism. The potential benefit is very modest (it could avoid a reversible adverse event) and the number screened is high, raising questions about the usefulness of this test in practice.⁶

When making decisions about whether to recommend diagnostic tests, clinicians should envision the actions that would occur based on the results. If findings would not change clinical strategies in ways that are likely to improve outcomes or reduce future testing, then the test probably should not be ordered. Platelet reactivity testing may currently fit into this category because the benefit is unclear.⁷ Ultimately, more evidence that addresses how particular testing strategies relate to patient outcomes is needed.

Decisions about testing need to consider the risks of the test itself as well as the downstream risks and benefits of the procedures and tests that may occur as a result of a positive test. For example, radiation exposure as a result of testing can be quite substantial.⁸ Moreover, even if a test does not have intrinsic risk, it may lead to more interventions, eventually resulting in net harm and wasteful use of scarce resources—a phenomenon designated the “cascade effect” by Mold and Stein.⁹ At every step of deciding about diagnostic testing, the clinician should be sure how a test result will be used and how it will promote the best interests of the patient.

Professional societies are now identifying tests that are not useful so as to reduce overuse of tests and procedures.¹⁰ The American College of Cardiology is producing *appropriate use criteria*, for guidance regarding the strength of evidence for tests and procedures in cardiovascular medicine.¹¹ The criteria state, “An appropriate diagnostic or therapeutic procedure is one in which the expected clinical benefit exceeds the risks of the procedure by a sufficiently wide margin such that the procedure is generally considered acceptable or reasonable care.” The methodology, shown in **Figure 4-1**, is based largely on expert opinion and the medical literature. It rates the tests and procedures into three categories: “appropriate,” “may be appropriate,” and “rarely appropriate.” The American College of Cardiology introduced these documents in 2005 with a focus on radionuclide imaging but has since expanded them substantially.

THERAPEUTIC DECISION MAKING

Decisions about therapy involve weighing risks and benefits to determine the best course of action, and understanding the goals of the patient. The key questions for clinical decision makers are whether an intervention can improve the quantity and/or quality of the patient's life, and how the risks, benefits, and requirements align with the patient's preferences. Moreover, the benefit is often best understood in a probabilistic framework, because most interventions do not provide a guaranteed benefit for each person who is treated.

Clinicians should be aware of the strength of the evidence in support of therapeutic decisions. The strongest evidence derives from well-conducted randomized trials. Observational studies and case series can provide useful information but usually are less definitive. Extrapolation from knowledge of pathophysiology provides the weakest evidence, because what seems reasonable does not always produce the expected outcomes when subjected to rigorous evaluation by trials. Regardless of design, clinicians should not assume that all published studies, including randomized trials, are high-quality and should not rely solely on summaries of studies. An understanding of the evidence requires the expert clinician to engage directly with the literature.

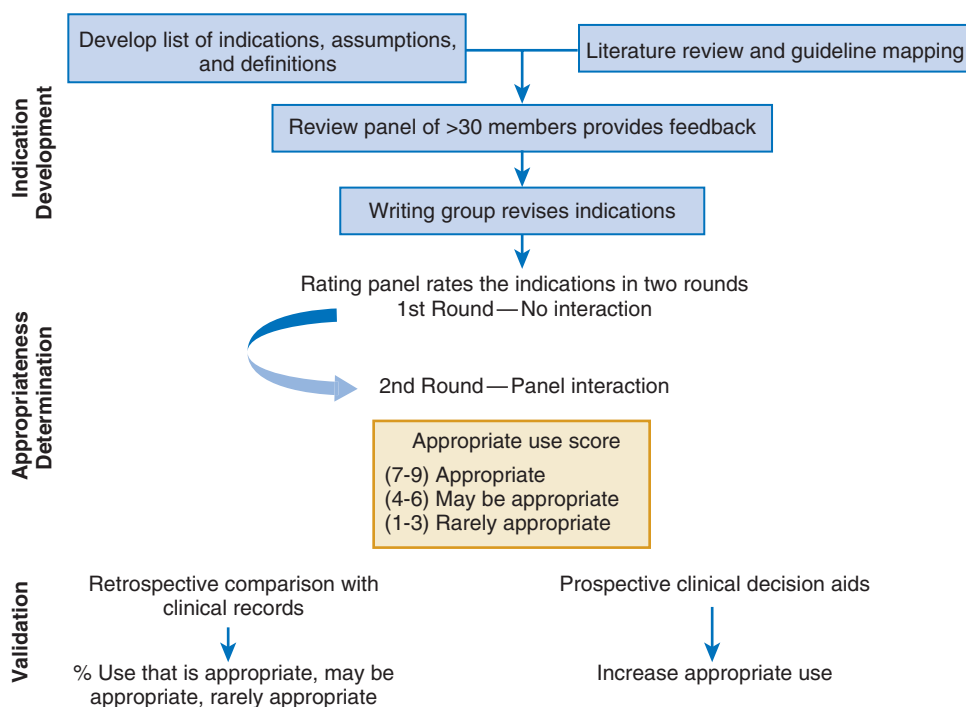

FIGURE 4-1 Appropriate use methodology.

Clinical practice guidelines from the American College of Cardiology and the American Heart Association synthesize the literature and provide recommendations with information about the strength and type of evidence.¹² Level of evidence A is associated with evidence derived from multiple randomized trials or meta-analyses. Level of evidence B is based on a single trial or nonrandomized trials or non-randomized studies. Level of evidence C is based solely on the consensus opinion of experts, case studies or standard-of-care, which may be derived primarily from causal reasoning. The recommendations are also organized into class I (should be performed or administered), II (some uncertainty, with IIa favoring treatment more strongly than IIb), and III (not recommended). Similar approaches, such as that of the European Society of Cardiology, are used internationally.

Unfortunately, even if high-quality studies are available, precise estimates of risks and benefits are not often available for individual patients. Although the internal validity of a study may be strong, the external validity, or generalizability, may be less clear, because patients in routine practice often do not resemble those enrolled in trials.¹³ Extrapolation of the trial results may be difficult. Moreover, the average effect may not be relevant for each patient.¹⁴

Decision Analysis

Decision analysis in medicine was developed to make explicit the assumptions that are relevant to a choice and reveal the expected outcomes, with the associated probabilities. The method takes into account the probabilities of different outcomes and the value (or utility) of various outcomes from the patient's perspective. By repeating the analysis with varying assumptions about probabilities and utilities, this approach can reveal the sensitivity of a decision to particular factors, and under what conditions a specific strategy is favored. A decision analysis cannot mandate a choice. It is a tool to assist in illuminating the trade-offs inherent in a decision that occurs under conditions of uncertainty.

Example: The decision about whether to administer fibrinolytic therapy to patients who are 80 years and older was controversial when the therapy was first introduced. Some clinicians had concerns that the bleeding risk might offset the benefit of restoring blood flow in the coronary artery. A decision analysis modeled the decision, incorporating estimates of the risks and benefits of therapy.¹⁵ In addition, the analysis evaluated the decision across a range of estimates for risk and benefit. The study demonstrated that across a broad range of estimates of risk and benefit, the decision to treat was, on average,

favored. The analysis provided the insight that even a small relative reduction in risk produced a substantial absolute reduction in the number of deaths that overshadowed the risk of bleeding. Using the best estimates for benefit, the decision favored treatment until the risk of hemorrhagic stroke rose to above 4%.

Evaluating the Evidence

The interpretation of evidence has many subtleties. Several topics bear particular emphasis, because they are commonly the source of misunderstanding, potentially leading to compromise in the quality of decisions.

P Values. Statistical issues play a key role in therapeutic decision making. The *P* value, in particular, has taken on great weight in clinical studies. This value represents the probability that the result observed, or a more extreme one, could have occurred under the null hypothesis. The *P* value does not convey the probability of the alternative hypothesis. In fact, under the right conditions, the probability that the null hypothesis is false may be low even with a *P* value less than 0.05.¹⁶ There are other views about how to approach statistical inference. Bayesian statisticians reject *P* values in favor of the approach of using data to update their estimates of a certain parameter. Support for the bayesian approach is growing, but hypothesis testing continues to dominate.¹⁷

Because the *P* value is so commonly used in clinical research, clinicians need to be aware of several key issues. First, the threshold of 0.05 for statistical significance is arbitrary. A *P* value of 0.04 implies that the data could occur 4% of the time if the null hypothesis is true, and a *P* value of 0.06 would suggest the data would occur 6% of the time. Is the difference between 6% and 4% enough to reject the null hypothesis in one case and accept it in another? Second, *P* values do not inform clinical importance. A large study sample can produce a small *P* value despite a clinically inconsequential difference between groups. Clinicians need to examine the size of the effects in addition to the statistical tests of whether the results could have occurred by chance.

Expressions of Benefit and Risk. Clinical decisions involve the balancing of benefit and risk. The expression of benefit and risk can influence decisions. Clinicians need to understand these expressions, which form the foundation for making decisions from clinical evidence.

The relative benefit (or risk) of an intervention is often expressed as a relative risk or odds ratio. *Risk* is the probability of an event, and *odds* is the probability an event will occur against the probability that it will not occur. A probability of 25% (1 in 4) represents odds of 1:3 or 1/3. The *relative risk ratio* of an event conveys the relative probability that an event will occur when two groups are compared. The *odds ratio* expresses the odds of the event in one group compared with another.

Despite its widespread use, the odds ratio is less helpful than relative risk in clinical decision making. The expressions are similar when baseline event rates are low (<5%) but deviate with higher risk and larger treatment effects.¹⁸ The odds ratio can express associations, but unlike the risk ratio, it cannot express the relative size of the treatment effect; if clinicians assume it to be equivalent to risk, it may lead to overestimates of the treatment effect when the outcome is common.

The relative benefit of any intervention may vary depending on patient characteristics, which are often explored in subgroup analyses. For example, fibrinolytic therapy was effective in the treatment of suspected acute myocardial infarction (AMI), and subgroup analyses revealed the benefit to be substantial in patients with ST elevation but not in those without it.¹⁹ The challenge is that subgroup analyses introduce the possibility that associations have occurred only by chance. In the Second International Study of Infarct Survival (ISIS-2), the investigators provided perspective on subgroup analyses by demonstrating that patients born under the astrologic sign of Gemini or Libra were significantly less likely to benefit from fibrinolytic therapy. Thus subgroup analysis is capable of producing important insights, but findings must be interpreted with caution.

A weakness of relative benefit estimates is that they do not convey information about what is achieved for patients at varying levels of risk. A small relative reduction in risk may be meaningful for a high-risk patient, whereas a large relative reduction may be inconsequential for a very low-risk patient. Absolute risk reduction, the difference between two rates, varies with the risk of an individual patient. For example, a risk ratio of 2.67 does not distinguish between baseline risks of 80% and 30% and between 0.08% and 0.03%. In one case, the absolute difference is 50% (5000/10,000) and in the other, it is 0.05% (5/10,000). In one case, 1 person of 2 is benefited and in the other, 1 of 2000 is benefited. Unfortunately, absolute benefit is not emphasized adequately in many articles.²⁰

NNT, which can be calculated as the inverse of the absolute risk reduction, represents the number of people who need to be treated to prevent an adverse event. NNTs constitute a useful approach to express risk and benefit that incorporates the patient's baseline risk and are a convenient way to express a trial result. For decision making with an individual patient, the baseline risk, which cannot be assumed to be the same as that of people in a trial, will strongly influence the estimate. Therefore, the NNT from a trial may need to be modified for an individual patient.

Example: Physicians and their patients are often in a position to decide about whether aspirin should be used for primary prevention of cardiovascular disease. To make the example easier, let us assume that the patient is male and a physician, the group for which the most data are available. Some of the best information about this topic is from the Physicians' Health Study (PHS) Research Group, which enrolled 22,071 doctors in a randomized, double-blind, placebo-controlled trial of the effect of 325 mg of aspirin every other day (versus placebo) on cardiovascular risk.²¹ The study was terminated early because the findings strongly favored aspirin. The investigators reported a 44% reduction in the risk of an AMI. The relative reduction sounds impressive, but the absolute reduction in risk is less compelling. The overall risk of an AMI in this population was low, 440 per 100,000 per year in the placebo group. Thus, a 44% reduction in a low-risk population averted only approximately 186 events per 100,000 treated (in the trial, 100 AMIs [93% nonfatal] were averted, with 54,560 per year of treatment). In other words, approximately 540 physicians needed to take aspirin every other day for a year for 1 person to avoid an AMI. The other 539 did not experience a benefit. On the other hand, there was a strong trend toward a doubling of the admittedly small risk of incurring a hemorrhagic stroke (relative risk, 2.14; 95% confidence interval, 0.96 to 4.77; $P = 0.06$). Overall, there were 11 extra hemorrhagic strokes. For every 9 AMIs that were avoided, there was 1 additional hemorrhagic stroke. The overall risk of stroke was slightly but nonsignificantly elevated in the aspirin group (relative risk, 1.22; 95% confidence interval, 0.93 to 1.60; $P = 0.15$), which also represented 11 extra strokes. The risk of death was not significantly different in the two groups (relative risk, 0.96; 95% confidence interval, 0.80 to 1.14; $P = 0.64$). The expression of the result

as an absolute risk reduction provides a perspective for the individual patient that is easier to understand than the relative reduction in risk. The main point is that the reporting of a large relative reduction in risk provides only part of the relevant information to make this decision, and that presentation can affect the decision.

Personalized Care

Patient characteristics should influence decisions. First and foremost, as noted in the section on shared decision making, the decision must be aligned with the patient's preferences, values, and goals. In addition, risk stratification should be used to estimate patient risk and to provide a perspective on the absolute risks and benefits. This approach generally uses the results of statistical models that have identified prognostic factors and incorporated them into a tool that may assist clinicians. For example, statin therapy may produce a substantial relative risk reduction but will have only a small benefit for those with the lowest risk.^{22,23} In another example, investigators found that only patients with a 10-year risk of cardiac events greater than 6% had a net benefit from aspirin therapy to prevent cardiovascular disease.²⁴ The presence of comorbid illnesses and competing risks also is important, because adding years of life is different from substituting causes of death. Socioeconomic status also may influence decisions. In countries in which patients bear the costs of health care, patients may need to make decisions based on affordability, and clinicians cannot be indifferent to these practical issues. Some studies also show that the comparative effectiveness of strategies may vary based on a patient's socioeconomic status.

Risk-Treatment Paradox

Several studies have shown a risk-treatment paradox in which the higher-risk patients are least likely to receive interventions that are expected to provide a benefit.^{25,26} This pattern is paradoxical in that the high-risk patients would be expected to have the most to gain from an intervention that reduces risk, assuming that the relative reduction in risk is constant across groups defined by their baseline risk. The source of the paradox is not known, although some investigators have suggested that it is related to an aversion to the treatment of patients with limited functional status.²⁷ This treatment pattern concentrates the intervention among the patients with the least absolute benefit. Clinicians may want to guard against this tendency.

Outcomes and Timing

Additional considerations in assessing the potential effect of interventions include the outcome that is evaluated and the time period assessed. Although articles about patients with cardiovascular disease often focus on cardiovascular events, including cardiovascular death, patients would be expected to have more interest in all-cause mortality. If averting cardiovascular death merely leads to death from other causes, then this focus is of little value for the patient. The issue is particularly important in older patients who have other conditions, often called competing risks.²⁸ Quality of life and health status are commonly neglected in clinical studies but are very important to patients. Patients may not value short-term mortality benefits if other conditions and complications diminish their quality of life during the time that is gained. Thus, narrowly focusing on specific outcomes may obscure important insights about an intervention. The challenge is that evaluating many outcomes in a trial can increase the likelihood of false-positive findings.

Surrogate Outcomes

In evaluating evidence, clinicians should be particularly attuned to the outcomes that are assessed. Ideally, interventions are assessed for their effect on a patient's quality or quantity of life. Many studies use surrogate outcomes, measures that are more distally related to the patient's experience but are expected to be related to a patient's quality or quantity of life. These surrogate outcomes often reflect information about a patient's biology and have prognostic value in epidemiologic studies. It is not possible, however, to know that an intervention that modifies a surrogate outcome has the expected

effect on patients. There are many examples in medicine of changes in surrogate measures that did not translate into benefits for patients (see Chapter 6).^{29,30} Clinicians evaluating the medical literature should know whether the outcome reflects the patient's experience. Prominent examples in which surrogates were not proxies for outcomes are studies of torcetrapib,³¹ dalceptrapib,³² niacin,³³ fenofibrate,³⁴ blood pressure,³⁵ and hemoglobin A_{1c} levels.³⁶ In the case of lipids, guidelines that focus on targets were based on extrapolations from clinical trials and accepted that low-density lipoprotein (LDL) levels were perfect surrogates for clinical outcomes, even as the literature increasingly failed to support that view.

Efficacy/Effectiveness

Efficacy is what is achieved by interventions under ideal circumstances, such as in the setting of a clinical trial. In contrast, effectiveness describes the effect in actual practice. There are many reasons why actual practice is different from the trial environment. Patients may differ in their biologic response or their adherence to intervention protocols and may be treated by less skilled physicians who have less infrastructure support. Therapeutic decisions are often based on the assumption that the efficacy and the effectiveness of interventions are identical, which is not always the case.

Completeness of Evidence

In evaluating the evidence, an additional consideration for clinicians is completeness of that evidence. The medical literature is skewed by publication bias. Such selective publication can distort the available evidence, compromise systematic reviews and meta-analyses, impair evidence-based clinical practice, and undermine guideline recommendations. Studies suggest that less than half of the trials registered in ClinicalTrials.gov, the Internet-based registry managed by the U.S. National Library of Medicine, were published.³⁷ Even trials funded by the National Institutes of Health are frequently not published.³⁸ Many trials that are published lack complete safety data.³⁹ Data that are not published can have important public health implications as was demonstrated in the case of Vioxx.⁴⁰ Clinicians are handicapped by not knowing what is absent from the literature and should at least be aware that information about the safety and effectiveness profile of interventions may not be complete. This unfortunate fact heightens the uncertainty surrounding treatment decisions.

External Factors

Clinicians frequently are faced with external influences that may affect their clinical decision making to the detriment of the best interests of patients. Defensive medicine, practiced to protect against future litigation, can expose patients to unneeded tests and procedures. Financial incentives, whether overt or hidden, should be excluded from the decision-making process. Any incentives that exist, even in the form of regular payment, should be transparent. Relationships with industry or others that could be perceived as compromising objectivity should be made clear to patients.

ACCURACY OF STUDY RESULTS

An important aspect of clinical decision making is the validity of the primary information on which the decisions are based. Clinicians need to ensure that the evidence is coherent and consistent. Errors can occur in analysis, interpretation, or reporting of results, and disagreement among experts is common. Excellent clinicians recognize the possibility that the information they have been provided is not correct, and they must be prepared to review primary data as necessary.

COGNITIVE ERRORS

Even with good information, cognitive errors can undermine clinical decisions.⁴¹ Some examples of these errors are described next.

Heuristics or Rules of Thumb

Clinicians tend to rely on heuristics, or rules of thumb, to assess probabilities and support complex cognitive tasks required for decision making. These heuristics can be useful because they allow shortcuts in reasoning, but they also are vulnerable to important errors and can undermine decisions.

Many medical heuristics are familiar. Occam's razor suggests that a clinician should choose the simplest explanation for a set of observations. Sutton's law, named for the bank robber who explained that he robbed banks "because that's where the money is," encourages clinicians to focus their attention where they will get the most yield.

A representative heuristic leads clinicians to estimate probability by how readily they can remember examples. Clinicians may estimate the probability of a disease because of its ease of recall. Thus, a more recent experience with a certain illness may make someone believe it is more common than it is. A clinical encounter in which the patient suffered a rare adverse event from a medication could lead a clinician to avoid that treatment. The anchoring heuristic leads people to stay with their initial impressions. This heuristic can mislead if clinicians do not refine initial impressions. A form of this heuristic, called premature closure, can lead clinicians to inappropriately stop pursuing alternative explanations.

Framing Effects

Like their patients, clinicians are sensitive to the framing of information. That is, the same truth is acted on differently, depending on the way the information is presented. Clinicians (and patients) need to recognize their sensitivity to the framing of the data. Clinicians are more likely to use a new therapy when presented with the relative reduction in risk, rather than the absolute reduction.^{42,43} Physicians can address this error by reframing decisions and being aware of the effect of the presentation of the data on perceptions of benefit.

Blind Obedience

The unwavering acceptance of the diagnosis of an authority (test or person) can lead to ignoring discordant information. Wise clinicians have the courage to question authority when the information does not provide a clear answer. The persistence of good decision makers and their refusal to blindly follow the crowd often lead to important insights. The best interests of the patient should guide clinicians and give them the strength to respectfully question authority, when appropriate.

SHARED DECISION MAKING

Clinical decisions are not the sole domain of physicians. Professional societies are moving to endorse the importance of shared decision making.^{44,45} The principle of autonomy mandates that patients retain control over their bodies and, except in rare circumstances, must consent to undergo interventions. Informed consent is the cornerstone of this concept, but other approaches that promote information sharing are also needed.^{46,47} Patients report that they want to be involved in decision making. One study of patients who had experienced an AMI found that two thirds preferred active engagement in decisions.⁴⁸

Shared decision making can be understood as having five phases: assess, advise, agree, assist, and arrange. The clinician must first assess the patient. Then the clinician should advise the patient of the options, including benefits and risks. Next, the clinician and the patient should agree on a plan that is aligned with the patient's preferences and values. The clinician should then assist the patient in implementing the plan. Finally, the patient and the clinician should arrange for follow-up evaluation.

Unfortunately, patients do not always have a good understanding of benefit and risk. For example, in a study of patients who had

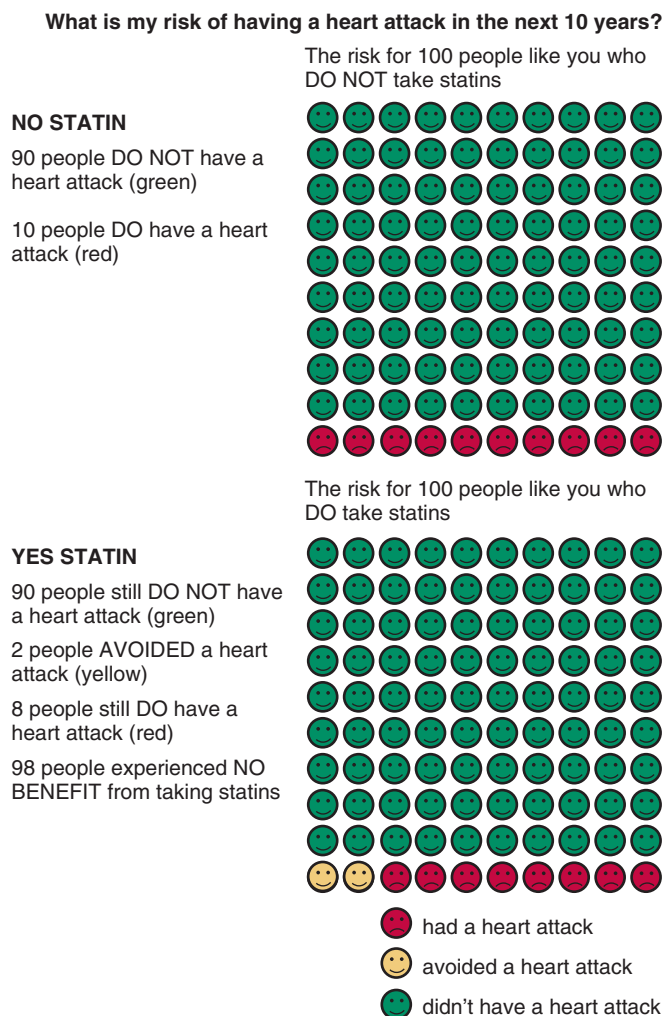

FIGURE 4-2 Decision support tool for acute myocardial infarction with and without use of statins. (Courtesy Dr. Victor Montori, Mayo Clinic, Rochester, Minn.)

consented to elective percutaneous coronary intervention (PCI), which does not improve survival or prevent AMI in this context, 75% thought it would prevent an AMI and 71% felt it would improve survival.⁴⁹ Moreover, only 46% could identify at least one possible complication. Among this group, 67% stated that for making decisions, they should be involved at least equally with the physician. Other studies also have found that patients often have unrealistic expectations of benefit.^{50,51}

Like physicians, patients are susceptible to framing effects.⁵² The manner in which information is presented, including the order in which it is provided, may be influential. Patients tend to view more favorably and be more likely to choose a therapy that is presented in relative rather than absolute terms, because the relative effect is almost always much greater than the absolute change.

Some techniques have been proposed to help clinicians convey risk and promote shared decisions.⁵³ First, clinicians should avoid descriptive terms such as “low-risk,” which may not have a consistent meaning among patients and may be difficult for them to interpret. In expressing risk as ratios, a consistent denominator should be used (e.g., 40 of 1000 and 5 of 1000 instead of 1 in 25 and 1 in 200). Clinicians should offer various perspectives to encourage multiple ways of considering risk and should use absolute numbers rather than relative risks. Visual aids also are useful to overcome barriers to understanding for patients with poor numeracy or literacy skills. Innovative approaches are emerging, including tools designed by experts for

use by clinicians and patients at the point of care^{54,55} (Figs. 4-2 and 4-3).

SYSTEMS OF CARE

It is important to view good clinical decision making as a team effort, rather than an individual skill. It is thus an effort that can occur only in the context of good systems. System errors, including problems with policies and procedures, and inefficient processes and communication obstacles, commonly contribute to incorrect information that fosters mistakes in decision making.⁵⁶ Lack of decision support can lead to overlooking sources of error. Lack of systems to diagnose and learn from decision-making errors will increase the likelihood that such errors will occur again.

CONCLUSIONS

Clinical decision making is the cornerstone of good clinical care. Physicians must not only have knowledge of the field but be prepared to use it in ways that optimize the care and outcomes of patients. Good judgment requires an ability to interpret evidence, weigh risks and benefits, and understand and promote the preferences and values of patients.

REFERENCES, 48

Although the quality of health care is important for all stakeholders, the primary perspective of this chapter is that of cardiovascular clinicians. Our goals are to help cardiovascular clinicians understand the definition and importance of quality of care, and the relevance of quality of care measurement and improvement in current cardiovascular practice. We focus on measuring health care quality and uses of quality measurements, as well as improving quality of care, with examples of *quality improvement* (QI) approaches.

DEFINING QUALITY OF CARE

Quality of care generally is defined as the extent to which health care delivery optimizes the outcomes, or the “end results,” of care. In the United States, the Institute of Medicine (IOM) has more specifically defined quality of care as “the degree to which health care systems, services, and supplies for individuals and populations increase the likelihood for desired health outcomes in a manner consistent with current professional knowledge.”¹ Key outcomes of care include survival, patient health status (i.e., symptom burden, functional status, and health-related quality of life), morbidity (e.g., acute myocardial infarction [MI] or heart failure hospitalization), patient experience (e.g., satisfaction), and cost-effectiveness.

The IOM has further proposed six domains of quality (Table 5-1), specifying that high-quality health care is effective, safe, equitable, timely, efficient, and patient-centered. Quality of care can thus be conceptualized as the extent to which these domains are optimized to improve outcomes of care. Accordingly, quality measures either should focus on at least one of these six domains of quality or should directly measure outcomes of care. QI is the action undertaken to improve one or more of these six domains in order to improve health outcomes.

Unfortunately, despite tremendous therapeutic advances in the past 50 years, well-recognized deficiencies in health care delivery are manifest, as suboptimal quality and outcomes of care persist. Health care spending in the United States exceeds that of any other country, but American health care does not achieve commensurately high scores on most metrics of quality of care or health outcomes.² Marked geographic variation in per capita health care utilization and spending are well recognized, yet consistent correlation between spending and health outcomes is lacking. For example, significant variation in the use of cardiovascular testing and procedures that is not explained by case-mix does not clearly translate into better patient outcomes.³

Numerous studies have documented *underuse* of guidelines-indicated care, unexplained variation in care delivery, and outcomes that may reflect *overuse* or inconsistent quality of care delivery, and

misuse, including avoidable complications and medical errors, all of which contribute to suboptimal outcomes. Gaps in quality can result from deficiencies in any of the IOM quality domains (see Table 5-1). For example, effective therapies may not be provided to eligible patients (e.g., statin therapy in a patient with a recent MI). Providers and health care systems may fail to minimize exposure of patients to unnecessary risk (e.g., prescribing drugs that carry a high risk of adverse drug-drug interaction). Clinicians may prescribe suboptimal or ineffective therapies (e.g., routine primary-prevention implantable cardioverter-defibrillator placement in a patient with mild left ventricular systolic dysfunction) or may recommend use of resource-intensive care for marginal benefit (e.g., routine intra-aortic balloon pump use for high-risk percutaneous coronary intervention). Care delivery may be excessively delayed or may be delivered differentially based on patient age, sex, race/ethnicity, or insurance status. Patients may not be engaged in their care to focus principally on the health outcomes of highest import (e.g., quality of life in addition to quantity of life). Deficiencies in any of these areas contribute to observed variations in quality of care and patient outcomes. These deficiencies, coupled with rising health care costs, have raised interest in health care reform, in which measurement and reporting of quality of care are central to clinical practice.

RELEVANCE OF QUALITY OF CARE IN CARDIOVASCULAR PRACTICE

Too often, cardiovascular clinicians perceive quality of care primarily as indicating more careful documentation in the medical record or satisfying quality metrics to meet payer or other requirements. This narrow view is reinforced in the current health care environment, in which quality measurement and reporting are often placed in a “regulatory” context and often are executed separately from clinician-patient interactions and clinical decision making. In reality, the interaction of patients and clinicians is central to high quality of care, in keeping with the impact of clinical decisions (e.g., therapeutics prescribed or procedures done) on patient outcomes. Hence, cardiovascular clinicians should play a central role in how quality is measured and how health systems are modified to optimize quality and patient outcomes.

Indeed, there are multiple reasons why cardiovascular providers should engage in quality of care measurement and improvement. First, quality of care reflects the degree to which clinicians practice evidence-based medicine. Inherent in evidence-based medicine is consideration of both the best available scientific evidence and individual patient factors and preferences. In an optimal scenario, informed patients, who understand the state of their health and the potential risks and benefits of health interventions ranging from prevention to acute and chronic disease management, interact with clinicians who observe the tenets of evidence-based medicine.

**TABLE 5-1** Institute of Medicine Domains of Highest-Quality Health Care

QUALITY DOMAIN	BRIEF DEFINITION
Effective	Providing services based on scientific knowledge to all who could benefit and refraining from providing services to those not likely to benefit (avoiding underuse and overuse, respectively)
Safe	Avoiding harm to patients from the care that is intended to help them
Equitable	Providing care that does not vary because of personal characteristics such as sex, ethnicity, geographic location, and socioeconomic status
Timely	Reducing waits and sometimes harmful delays for both those who receive care and those who give care
Efficient	Avoiding waste, including the waste of resources and patient time, as well as waste of equipment, supplies, ideas, and energy
Patient-centered	Providing care that is respectful of and responsive to individual patient preferences, needs, and values, and ensuring that patient values guide all clinical decisions; this type of care attends to patients' physical and emotional needs, maintaining or improving their quality of life, and gives them the opportunity to be the locus of control in decision making.

From Institute of Medicine, Committee on Quality Health Care in America: *Crossing the Quality Chasm: A New Health System for the 21st Century*. Washington, DC, National Academies Press, 2001.

Second, quality of care is increasingly tied to maintenance of certification and licensure, particularly with regard to involvement in practice improvement. Medical education is evolving to a model of life-long learning, in which the principles of quality of care are integrated with clinical knowledge and decision making. Intrinsic to this new framework, cardiovascular clinicians will need to have the skills of quality of care measurement and improvement in addition to medical knowledge.

Third, quality of care lies at the center of health care system improvement. The outcomes of health decisions of patients and cardiovascular clinicians depend on the environment (including community and health care system attributes) in which these decisions are made. From the perspective of the cardiovascular clinician, quality of care includes not only their actions but also patient access, engagement, and behavior; the context and methods of health care delivery; and multiple aspects of the health care system, ranging from information technology support to ancillary personnel support to health system policy and incentives. Ultimately, although clinical knowledge and skill are essential for high-quality care, they are not sufficient; a primary driver of high-quality health care and QI is the health care delivery system.

Finally, quality of care provides a means for professional accountability. In today's health care environment, performance-based reimbursement and public reporting of quality of care measures are increasingly prevalent. Evolving models of health care delivery and reimbursement that are being pursued in the United States, such as accountable care organizations and integrated delivery systems, invariably emphasize performance on quality measures that reflect one or more of the IOM quality domains (see [Table 5-1](#)) and the direct measurement of patient outcomes. Measures of health care value (outcomes as a function of costs of care) are increasingly used to characterize cardiovascular practice, including linkage to incentives or disincentives, or both.

Cardiovascular clinicians should therefore have a strong interest in participating in robust and clinically relevant quality of care measurement and improvement efforts, health care delivery design and payment programs. Moreover, the concept of professionalism includes not only clinical knowledge but also excellence in the delivery of health care and accountability for that care. Quality of care—through measurement and improvement of the IOM domains of quality and patient outcomes—directly speaks to health care delivery and accountability. Accordingly, quality of care is central to professionalism in cardiovascular medicine.

TABLE 5-2 Current American College of Cardiology/American Heart Association (ACC/AHA) Performance Measure Sets

TOPIC AREA	PUBLICATION YEAR (WITH UPDATE)	PARTNER ORGANIZATIONS
Heart failure	2005 (2011)	ACC/AHA (inpatient) ACC/AHA/AMA-PCPI (outpatient)

MEASURING HEALTH CARE QUALITY AND USES OF QUALITY MEASUREMENTS

This section discusses types of quality measures, the uses of measures, commonly used data sources for quality measurement, and possible limitations of quality measures, including the potential for unintended consequences.

Types of Quality Measures

Donabedian's seminal treatise, published more than 50 years ago, delineated a conceptual framework for measuring health care quality that endures to the present: characterizing quality according to structure, process, and outcome.⁴ Although measurement has extended beyond these three domains, these constructs remain central to understanding the quality of health care. The American College of Cardiology/American Heart Association (ACC/AHA) have described in detail the methodologic principles of developing various types of measures.⁵⁻⁸

Structural measures are specific attributes of the health care delivery system that are used as surrogates for the care delivered. Examples are procedural volume and accreditation status. In general, such measures are only weak surrogates and frequently are considered inadequate if more robust metrics of quality are available.^{9,10}

Process measures reflect the actions of providers, such as the prescription of a medication, and are among the most commonly used metrics of quality. For example, the Centers for Medicare & Medicaid Services (CMS) has used processes of care for acute MI and heart failure as part of its Hospital Compare quality reporting system since 1995¹¹; the ACC/AHA have developed several sets of process measures for specific cardiovascular procedures and conditions ([Table 5-2](#)). Operationally, process measures are generally selected from among the care processes with strong support in practice guidelines (e.g., class I recommendations in the ACC/AHA

TABLE 5-3 Attributes of Measures of Process, Outcome, and Value in Health Care

MEASURE TYPE	MEASURE ATTRIBUTES
Process ⁵	Evidence-based Interpretable Actionable Explicit numerator and denominator Valid Reliable Feasible
Outcomes ⁶	Clear explicit definition of appropriate patient sample Clinically coherent variables for risk adjustment Sufficiently high-quality and timely data Designated time of covariate and outcome ascertainment Standardized period of outcome assessment Analysis accounting for multilevel organization of data Disclosure of methods used
Value/efficiency ⁷	Integration of both quality and cost Valid cost measurement and analysis No or minimal incentive to provide poor-quality care Proper attribution of the measure

guideline recommendation taxonomy). Not all strong guideline recommendations are appropriate for adoption as quality measures, however; such measures should possess additional attributes that support their use for quality measurement (Table 5-3).

Process measures have substantial face validity because they focus on therapies and approaches that have been established in clinical studies and are readily interpretable. However, they generally require clinical data, thus requiring resources for data abstraction. The exclusion of individual patients from a process measure denominator because of contraindications to treatment is viewed favorably by clinicians but is controversial. Such exclusions increase the burden of data collection but enhance the clinical validity of these measures. Moreover, there is not always a demonstrated association between higher performance on process measures and better patient outcomes.¹² Finally, process measures may “top out,” in that performance is consistently high and the measures lose the capacity to discriminate meaningfully among institutions, as has been the case with many of the process measures for acute MI and heart failure that are reported to the public.¹³

In view of the limitations of structural and process measures, a greater emphasis has been placed on outcomes measures. Suitable outcomes measures have several attributes (see Table 5-3), perhaps the most important of which is risk adjustment.⁶ Risk, or “case mix,” adjustment can address concerns that differences in outcomes reflect differences in patient populations being cared for. Robust risk adjustment requires advanced statistical methods, and is generally limited by the extent of availability of accurate data variables (e.g., patient characteristics) to include in risk models. Outcome measures are appealing because they are patient-centered, can be applied to all patients (as opposed to process measures, which apply only to a discrete “denominator” of patients), and reflect the actions of the health care system.¹⁴ Risk adjustment methods must be valid, however, and some outcomes of great importance to patients such as health status are not currently measured systematically in large populations. Furthermore, unlike process measures, outcomes measures do not explicitly inform the targets for QI.

Measures of value—broadly defined as quality delivered as a function of cost—have emerged as part of the quality measurement portfolio.¹⁵ Of importance, cost alone is not synonymous with value; the easiest way to minimize cost is to withhold care, whereas value explicitly incorporates quality. Attributes of measurements of value have been enumerated (see Table 5-3);⁷ developing robust measures

of value involves the challenges attendant to measuring quality as well as those associated with measuring costs.

In response to escalating costs and concerns that variation in care delivery may in part reflect overuse, the ACC, in conjunction with partner societies, have developed *appropriate use criteria* (AUC). These criteria provide ratings of the appropriateness of care for several cardiovascular diagnostic and therapeutic modalities for a range of commonly encountered clinical scenarios.¹⁶ Because the AUC are based on clinical scenarios that may not exactly reflect individual patient situations, and because the criteria are derived from expert consensus, their role in quality measurement and reporting is evolving.

Composite measures, which formally aggregate multiple aspects of quality, are appealing because of the various structures, processes, and outcomes that can be measured for a particular condition or procedure.¹⁷ Developing composite measures is complex, and should be guided by an explicit methodology.¹⁸ These measures have the advantage of combining various domains of quality but can obscure the impact of component measures and can decrease the understanding of where action for improvement is needed.

Data Sources

In general, quality measures are most useful when compared against an external standard (e.g., a “benchmark” of similar practice or national performance). Although single-center data can on occasion provide useful insights for local quality assessment and improvement, data used to characterize quality are most useful when compared across patients, providers, and settings. Sources meeting these criteria are often categorized as “claims” (also known as “administrative”) data or clinical data, each of which has distinct strengths and limitations. Ultimately, any measurement of quality will be no more robust than the quality of the data upon which it is based.

Insurance payers maintain data bases of claims for services as a means of identifying and paying for health services delivered to their members. Claims data have several strengths. First, they tend to include large numbers of patients, although this depends on the payer involved. Second, because these data are already collected for other purposes, there is lower incremental expense to use claims data for this purpose. Finally, claims data use a consistent standard (e.g., International Classification of Diseases [ICD]-9 codes) for each claim.

However, several factors significantly limit the value of claims data. Because their primary purpose is to facilitate billing, claims data are constrained in their capacity to inform clinical inferences. For example, claims data are limited with regard to measuring severity of disease, indications and results of procedures, and differentiating comorbid conditions from complications. Moreover, diagnostic codes may be discordant with clinical diagnoses established by clinicians.¹⁹ Claims data also are specific to the population receiving insurance from the entity that creates the data base. Finally, claims data require substantial time to elapse before they are adequately complete for use. Thus measurements with these data will lag with respect to current practice. The usefulness of claims data as a component of quality measurement is largely dependent on the specific use. In some cases, claims and clinical data perform similarly for case mix adjustment at the institutional or hospital level for cardiovascular conditions.²⁰ However, when used for risk adjustment of outcomes at the patient level, clinical data generally provide better calibration and discrimination than claims data alone.²¹

Clinical data are appealing as the foundation of quality measurements for several reasons. The primary advantage of clinical data is their specificity with regard to clinical details, such as severity of disease, coexisting conditions, and indications for and results of procedures. For example, identifying contraindications to the use of a particular medication in a quality measure is likely to be incomplete using claims data, whereas clinical data are more likely to include the relevant information. Limitations to clinical data also are recognized. Clinical data generally are more expensive and difficult to obtain in large populations compared with claims data. Aside from national clinical registry programs (discussed further on), there are few sources of clinical data using consistent data standards and adequate in reach and scope to characterize quality on a large scale. Data in medical records, including electronic health records (EHRs), typically do not use standardized definitions and may not include the specific elements necessary to compose a quality measure.

National clinical registry programs are currently the most widely used clinical data to measure quality. In the United States, the National Cardiovascular Data Registry program of the ACC and partner organizations (www.ncdr.com), the AHA Get With the Guidelines program (www.heart.org), and the Society of Thoracic Surgeons (STS) National Database (www.sts.org) are the most widely implemented cardiovascular registry programs. These programs provide quality measurements with national benchmarks using detailed standardized clinical data and can support QI initiatives.²²

In some cases, clinical and claims data are used together for quality measurement purposes. This approach is often used to take advantage of the detailed clinical data from a registry program for a specific episode of care (e.g., a percutaneous coronary intervention or a hospitalization for heart failure) and the assessment of events after that episode from claims data (e.g., death or rehospitalization). These hybrid data sources, though sharing the advantages and disadvantages of their component sources, can permit assessments of longitudinal outcomes with a robust clinical foundation.

The increasing deployment of EHRs in the United States creates opportunities and challenges for quality measurement. EHRs have potential as sources of large amounts of clinical data but do not constitute a panacea for how to measure quality. EHRs are not superior to paper records with respect to data structure and definitions, or in ensuring that particular data are collected, unless they are specifically modified to do so. Moreover, EHR systems are not necessarily interoperable among institutions, limiting the extent to which they can be used for multi-institutional quality assessment without further efforts. Experience suggests that EHRs must evolve considerably to achieve their full potential as a source of robust, reliable data for quality measurement.²³

Uses of Quality Measures

Quality measurements serve a range of purposes, but in broad terms they can be considered as supporting QI (see later section, [Improving Quality of Care](#)) or accountability for care (e.g., public reporting).²⁴ The distinction between these two uses is important: Although a broad range of measures may be suitable for the purposes of self-evaluation, benchmarking, and informing QI, measures that will be used for accountability must withstand the scrutiny of those who are measured and the intended consumers of those measures.²⁵ The use of measures for accountability requires greater validity, reliability, and reproducibility of the measures, including the quality of the data that underlie the measures, as well as attribution of the measures.²⁶ The ACC/AHA and other measure developers apply specific standards and nomenclature to identify those measures that are appropriate for accountability purposes (e.g., those designated as “performance measures”) or those that are intended for QI purposes (designated as “quality metrics” or “test metrics”).²⁵ In the United States, most measures intended for the purposes of accountability are reviewed and endorsed by the National Quality Forum (www.nqf.org).

The past two decades have witnessed the evolution of programs that use quality measures for the purposes of accountability. These include public reporting of quality measures (e.g., CMS Hospital Compare); “pay for reporting,” whereby participation in reporting efforts (but not the specific results) results in financial incentives; and “pay for performance,” whereby reimbursement is tied to the specific results of outcomes (e.g., the CMS Value-Based Purchasing program). Professional organizations also are taking leadership roles in public reporting efforts based on clinical registry data, such as the STS voluntary public reporting program for cardiovascular surgery.²⁷

Ostensibly, accountability programs are intended to improve quality by introducing meaningful incentives for better performance. Systematic reviews of the existing literature suggest that although public reporting stimulates efforts to improve quality,²⁸ there is not consistent evidence that it results in better quality or influences decisions by the consumers of health care services.^{29,30} The heterogeneous results of accountability programs likely reflect the variability in these programs in terms of what is measured, the contexts of implementation, and the incentive structures.

Concerns About Quality Measures: Unintended Consequences

Efforts to measure and improve quality can potentially result in unintended consequences. For example, focusing on one process of care could detract from attention to others; incentives to increase rates of treatment could result in overtreatment in some cases; or threats of penalties for providers for adverse procedural outcomes or inadequate risk adjustment methods could result in biases against performing that procedure in high-risk patients.^{31,32} These concerns support the importance of monitoring for potential unintended consequences as part of performance improvement efforts and programs. To date, however, QI and accountability efforts generally have not been evaluated with the rigor and to the extent of other medical interventions.³³ Accountability also may incentivize “gaming” the measurement system, which undermines its credibility with regard to meaningful QI and increases the importance of rigorous data quality/audit programs.

Improving Quality of Care

The principal reason to measure quality of care should be to inform meaningful improvement in health care delivery. As noted, QI, often also referred to as performance improvement, is the set of actions undertaken to improve one or more of the six IOM domains of quality (see [Table 5-1](#)) in order to improve health outcomes. Various studies have helped delineate key components of successful QI efforts, yet a number of activities familiar to cardiovascular clinicians have been found to be largely ineffective.

Imploring clinicians to “do more” or “do better” in terms of following guidelines or documenting care is generally ineffective. Perhaps surprisingly, traditional continuing medical education and didactic lectures, utilization management, and the availability of clinical practice guidelines also are ineffective in achieving QI.³⁴ On the other hand, the availability of quality measures with benchmarking (also called “audit and feedback”) can be successful, particularly when tied to health care delivery system improvement.

Successful QI involves identifying suboptimal performance in one or more aspects of quality of care, and then matching QI activities to effectively improve performance. Data with benchmarking is central to choosing meaningful targets for improvement (see [Fig. 5-1](#)). Once QI targets are chosen, a primary emphasis for QI activities should be system changes to support higher quality care delivery. Examples are use of the EHR for computerized order entry to avoid prescription errors and to provide automated drug-drug interaction alerts, development of and adherence to standardized order sets and care pathways (e.g., for acute MI patients), implementation of a multidisciplinary care team approach, efforts to promote care coordination, and effective engagement of patients in decision making.

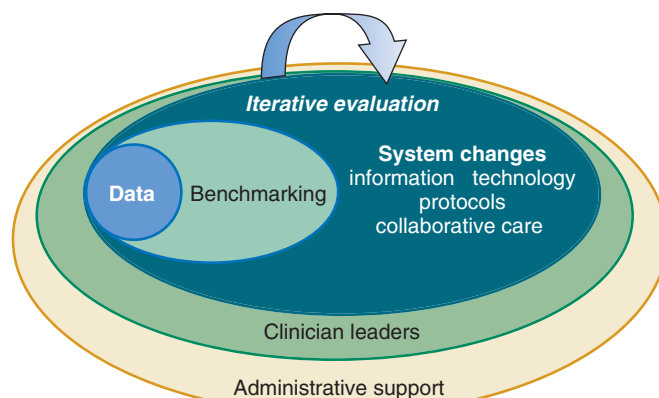

FIGURE 5-1 Key components of quality improvement. (From Rumsfeld JS, Dehmer GJ, Brindis RG: *The National Cardiovascular Data Registry: Its role in benchmarking and improving quality*. *US Cardiol* 6:11, 2009.)

QI is most successful as a “team sport”; it should be focused not on an individual clinician but on a multidisciplinary team. Moreover, QI should be responsive to specific gaps in performance over time, striving to continuously improve the delivery system. QI efforts should be evaluated in an iterative fashion, to assess progress in performance improvement and to monitor for unintended consequences. The measurement of the impact of QI, which can be considered part of “health care delivery research,” should be increasingly important in the future.³⁵

Clinical leaders—those who are engaged in and committed to quality measurement and improvement—are critical to successful QI efforts. Increasingly, training in quality measurement and QI is available to cardiovascular clinicians. Many hospitals and health systems are training clinical staff in quality. Organizations such as the ACC are embedding quality measurement and performance improvement into educational programs; these programs will increasingly support the performance improvement requirements of maintenance of certification and licensure.

Administrative support also is crucial for successful QI. This includes not only financial support of quality measurement and improvement efforts, but also clear institutional leadership goals and commitment with regard to achieving the highest quality of care. Indeed, among the most consistent and powerful drivers of QI is the culture of a practice or institution. For example, in an evaluation of hospital characteristics associated with 30-day mortality rates after acute MI, those hospitals that fostered “an organizational environment in which clinicians are encouraged to solve problems creatively” had, in addition to having both physician and nurse quality champions, significantly lower mortality rates.³⁶

QI may be carried out at local levels (i.e., community/practice/hospital) or at regional, health system, national, or international levels. In other words, QI goals and strategies for performance improvement can be defined as part of local or broader-reaching quality initiatives; however, the principles of QI are the same for each of these, and the QI activities ultimately must be executed at the local level following the key factors noted in Figure 5-1. Several well-known approaches to QI are briefly described in the remainder of this section, including Plan-Do-Study-Act (PDSA), Lean, and Six Sigma.

Some Approaches to Quality Improvement

Fruitful QI requires the integration of the components described previously (see Fig. 5-1) into a specific framework for action. Perhaps the most widely used framework for QI in health care is PDSA. This model—developed by Associates in Quality Improvement (www.aqiweb.org)—has been embraced by the Institute for Healthcare Improvement as the approach to plan health QI (www.ihl.org). PDSA is composed of two interdependent steps: first, formulating a plan by setting goals, establishing metrics of success, and identifying changes to implement; and second, testing these changes in an iterative PDSA cycle (Fig. 5-2). The goals should be measurable, time-delimited, and realistic. The measures should address at least one of the IOM domains of quality (see Table 5-1) but should also include ways to characterize possible adverse consequences of the improvement effort. Then, in evaluating changes, each step of the PDSA cycle contributes to the understanding of the impact of the change, both positive and negative, thus informing future cycles of improvement.

The Lean approach builds on PDSA by specifically targeting wasteful health care processes. Lean was originally developed at Toyota to improve the efficiency of production of automobiles. Not surprisingly, with the rapid growth of medical expenditures and the understanding that more spending does not necessarily translate to better quality, the use of Lean in health care settings has expanded rapidly. In essence, the Lean QI approach includes a focus on patient needs, an explicit evaluation of complex processes of care delivery in a given setting, and the identification and improvement of those components of the process that do not promote one or more of the IOM domains of quality (see Table 5-1) for improvement. The process of care mapping (e.g., the specific steps of how care is delivered in the emergency room, on a ward, or in the office), empowering all members of the health care team to help identify targets, and improving delivery in an iterative fashion are hallmarks of Lean.³⁷ Studies of the Lean approach suggest that it is an effective means of improving efficiency, by both reducing cost and improving quality.

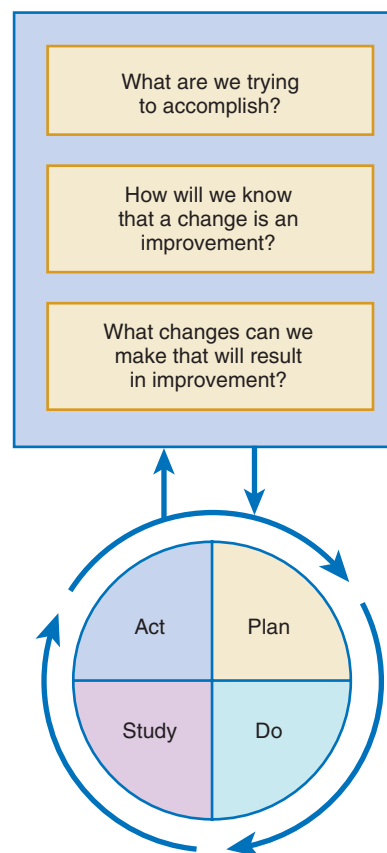

FIGURE 5-2 The PDSA (Plan-Do-Study-Act) cycle of quality improvement. (From the Institute of Healthcare Improvement [www.ihl.org], attributed to Langley GJ, Nolan KM, Nolan TW, et al: *The Improvement Guide: A Practical Approach to Enhancing Organizational Performance*. 2nd ed. San Francisco, Jossey-Bass Publishers, 2009.)

Another well-known QI approach that builds on PDSA is Six Sigma, which focuses on reducing unnecessary variation in care delivery. The term *Six Sigma* stems from statistical process control, which aims to execute care processes with error rates that are six standard deviations below average. Unfortunately, medical errors generally occur at much higher rates.³⁸ Hence, Six Sigma emphasizes reducing errors in processes of care such as medication prescriptions or medical procedures (i.e., minimizing unnecessary procedural complications) through five steps, which constitute a modification of PDSA—namely, Define, Measure, Analyze, Improve, and Control.³⁹ The last step emphasizes ongoing monitoring of care processes once error rates/variation has been reduced, such that additional QI can be applied if variation/error rates increase. Lean and Six Sigma may be combined (Lean Six Sigma) for QI that leverages a PDSA approach to target reductions in wasteful processes of care and minimizing variation/error rates in care delivery.

CONCLUSIONS

Quality of care—the extent to which health care delivery optimizes patient outcomes—is becoming a core competency for cardiovascular clinicians. It is the practice of evidence-based medicine as well as accountability of care, both of which help define professionalism. Quality, or performance, improvement is increasingly central to clinical training and life-long medical education for cardiovascular clinicians, including maintaining certification and licensure.

Quality measurement and improvement are now an essential part of cardiovascular practice, as well as for the broader health care system. Quality measures—be they structural, process, outcome, value, or composite—depend on the extent of underlying scientific evidence, the validity of data sources, and clear specification. They can be used for QI as well as in accountability programs such as public reporting and “pay for performance.” Meaningful QI stems

from using data with benchmarking to identify targets for improvement, making system changes to support high-quality care delivery, and having adequate clinical leadership as well as administrative support. Robust, iterative evaluation of QI efforts is of critical importance, both to assess the impact of these efforts on intended quality measures and to monitor for unintended consequences.

Ultimately, cardiovascular clinicians should be fully engaged in quality of care, to help ensure that quality measurement, QI, and accountability programs are clinically meaningful, not just a regulatory burden. Only in this way will quality of care efforts truly promote health care that is more effective, safe, equitable, timely, efficient, and patient-centered and that translates into improved patient outcomes.

Despite many decades of advances in diagnosis and management, cardiovascular disease (CVD) remains the leading cause of death in the United States and other high-income countries, as well as many developing countries.¹ Managing the burden of CVD consumes 16% of overall national health care expenditures in the United States; interventions to treat CVD are therefore a major focus of contemporary clinical research. Therapeutic recommendations are no longer based on nonquantitative pathophysiologic reasoning but instead are evidence-based. Rigorously performed trials are required before regulatory approval and clinical acceptance of new treatments (drugs, devices, and biologics) and biomarkers.² Thus the design, conduct, analysis, interpretation, and presentation of clinical trials constitute a central feature of the professional life of the contemporary cardiovascular specialist.^{3,4} Case-control studies and analyses from registries are integral to epidemiologic and outcomes research but are not strictly clinical trials and are not discussed in this chapter.^{5,6}

CONSTRUCTING THE RESEARCH QUESTION

Before embarking on a clinical trial, investigators should review the FINER criteria for a good research question (Table 6-1) and the phases of evaluation of new therapies (Table 6-2) and should familiarize themselves with the processes of designing and implementing a research project, good clinical practice, and drawing conclusions from the findings (Fig. e6-1).^{3,4,6-10} A clinical trial may be designed to test for superiority of the investigational treatment over the control therapy but also may be designed to show therapeutic similarity between the investigational and the control treatments (noninferiority design) (Fig. 6-1; Table 6-3).

In a noninferiority trial, investigators specify a noninferiority criterion (M) and consider the investigational treatment to be therapeutically similar to control (standard) therapy if, with a high degree of confidence, the true difference in treatment effects is less than M (see Fig. 6-1).^{11,12} Specification of the noninferiority margin M involves considerable discussion between the investigators (advocating for clinical perception of minimally important difference) and regulatory authorities (advocating for assurance that the investigational treatment maintains a reasonable fraction of the efficacy of the standard treatment based on previous trials).^{11,12} The investigational therapy may satisfy the definition of noninferiority but may or may not also show superiority over the control therapy.¹³ Thus superiority can be considered a special case of noninferiority, in which the entire confidence interval for the difference in treatments falls in favor of the investigational treatment (see Fig. 6-1). Investigators can stipulate that a trial is being designed to test both noninferiority and superiority (see Table 6-3). For a trial that is configured as a noninferiority trial, it is acceptable to test for superiority conditional on having demonstrated noninferiority.¹⁴ Because of the subjective nature of the choice of M, the reverse is not true—trials configured for superiority cannot later test for noninferiority unless the margin M was prespecified.

Regardless of the design of the trial, it is essential that investigators provide a statement of the hypothesis being examined, using a format

that permits biostatistical assessment of the results (see Fig. e6-1). Typically, a null hypothesis (H_0) is specified (e.g., no difference exists between the treatments being studied) and the trial is designed to provide evidence leading to rejection of H_0 in favor of an alternative hypothesis (H_A) (a difference exists between treatments). To determine whether H_0 may be rejected, investigators specify type I (α) and type II (β) errors, referred to as the false-positive and false-negative rates, respectively. By convention, α is set at 5%, indicating a willingness to accept a 5% probability that a significant difference will occur by chance when there is no true difference in efficacy. Regulatory authorities may on occasion demand a more stringent level of α —for example, when a single large trial is being proposed rather than two smaller trials—to gain approval of a new treatment. The value of β represents the probability that a specific difference in treatment efficacy might be missed, so that the investigators incorrectly fail to reject H_0 when there is a true difference in efficacy. The power of the trial is given by the quantity $(1 - \beta)$ and is selected by the investigators—typically, between 80% and 90%.⁷ Using the quantities α , β , and the estimated event rates in the control group, the sample size of the trial can be calculated with formulas for comparison of dichotomous outcomes or for a comparison of the rate of development of events over a follow-up period (time to failure). Table 6-3 summarizes the major features and concepts for superiority and non-inferiority trials designed to change the standard of care for patients with a cardiovascular condition.

CLINICAL TRIAL DESIGN

Controlled Trials

The *randomized controlled trial* (RCT) is considered the gold standard for the evaluation of new treatments (Fig. 6-2). The allocation of subjects to control and test treatments is not determined but is based on an impartial scheme (usually a computer algorithm). Randomization reduces the likelihood of patient selection bias in allocation of treatment, enhances the likelihood that any baseline differences between groups are random so that comparable groups of subjects can be compared, and validates the use of common statistical tests. Randomization may be fixed over the course of the trial or may be adaptive, based on the distribution of treatment assignments in the trial to a given point, baseline characteristics, or observed outcomes (see Fig. 6-2A).¹⁵ Fixed randomization schemes are more common and are specified further according to the allocation ratio (equal or unequal assignment to study groups), stratification levels, and block size (i.e., constraining the randomization of patients to ensure a balanced number of assignments to the study groups, especially if stratification [e.g., based on enrollment characteristics] is used in the trial). During the course of a trial, investigators may find it necessary to modify one or more treatments in response to evolving data (internal or external to the trial) or a recommendation from the trial's data safety monitoring board (DSMB)—that is, to implement an *adaptive* design (see Fig. 6-2B).¹⁵ Adaptive designs are most readily implemented during phase II of therapeutic

COMPARING SUPERIORITY AND NONINFERIORITY DESIGNS		
	Null hypothesis	Alternative hypothesis
Superiority	$H_0 : P_{\text{Test}} = P_{\text{Control}}$	$H_A : P_{\text{Test}} < P_{\text{Control}}$
Noninferiority	$H_0 : P_{\text{Test}} \geq P_{\text{Std}} + M$	$H_A : P_{\text{Test}} < P_{\text{Std}} + M$

FIGURE e6-1 Statistical design of superiority and noninferiority trials. In both superiority and noninferiority trials, the investigators propose a null hypothesis (H_0) with the goal of the trial being to reject H_0 in favor of the alternative hypothesis (H_A). To determine whether the null hypothesis may be rejected, before initiation of the trial, the type I (α) and type II (β) errors are specified (*not shown*). In superiority trials, α is usually two-sided, whereas it is one-sided in noninferiority trials. The quantity $(1 - \beta)$ is referred to as the power of the trial. M = margin for noninferiority. P_{Std} = proportion of subjects experiencing the event of interest in the standard treatment group.

development. Regulatory authorities are concerned about protection of the trial integrity and the studywise alpha level when adaptive designs are used in registration pathway trials.¹⁵ The most desirable situation is for the control group to be studied concurrently and to comprise subjects distinct from those of the treatment group. Other trial formats that have been used in cardiovascular investigations include nonrandomized concurrent and historical controls (**Fig. 6-3A, B**), crossover designs (see **Fig. 6-3C**), withdrawal trials (see **Fig. 6-3D**), and group or cluster allocations (groups of subjects or investigative sites are assigned as a block to test or control). Depending on the clinical circumstances, the control agent may be a placebo or a drug or other intervention used in active treatment (standard of care).

TABLE 6-2 Phases of Evaluations of New Therapies

PHASE	FEATURES	PURPOSE
I	First administration of new treatment	Safety—is further investigation warranted?
II	Early trial in patients	Efficacy—dose ranging, adverse events, pathophysiologic insights
III	Large scale comparison versus standard treatment	Registration pathway—definitive evaluation
IV	Monitoring in clinical practice	Postmarketing surveillance

Modified from Meinert C: *Clinical trials. Design, conduct, and analysis*. New York, Oxford University Press, 1986; and Stanley K: *Design of randomized controlled trials*. *Circulation* 115:1164, 2007.

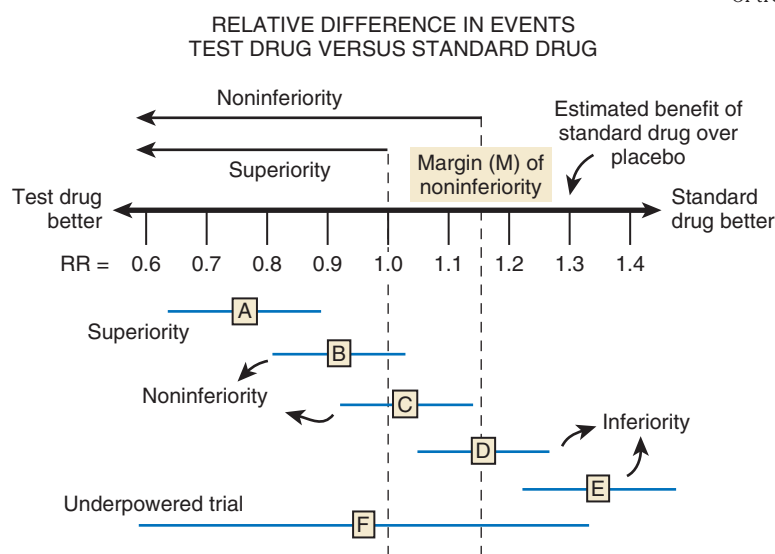

FIGURE 6-1 Example of design and interpretation of noninferiority trials. The margin (M) for noninferiority is prespecified based on previous trials comparing the standard drug with placebo. Examples of hypothetical trials A to F are shown, of which some (trials B and C) satisfy the definition of noninferiority. Trial A not only satisfies the criteria for noninferiority but, because the confidence interval is entirely to the left of a relative risk of 1.0, also shows superiority of the test drug over the standard drug.

Other Forms of Controlled Studies

Trials in which the investigator selects the subjects to be allocated to the control and treatment groups are *nonrandomized, concurrent control studies* (see **Fig. 6-3A**). In this type of trial design, clinicians do not leave the allocation of treatment in each patient to chance, and patients are not required to accept the concept of randomization. It is, however, difficult for investigators to match subjects in the test and control groups for all relevant baseline characteristics, introducing the possibility of selection bias, which could influence the conclusions of the trial. Clinical trials that use *historical controls* compare a test intervention with data obtained earlier in a nonconcurrent, nonrandomized control group (see **Fig. 6-3B**). Potential sources for historical controls include previously published trials in cardiovascular medicine and electronic data bases of clinic populations or registries. The use of historical controls allows investigators to offer the treatment(s) being investigated to all subjects enrolled in the trial. The major drawbacks are the potential for bias in the selection of the control population and failure of the historical controls to reflect accurately the contemporary picture of the disease under study.

The *crossover design* is a special case of the RCT in that each subject serves as his or her own control (see **Fig. 6-3C**). The appeal of this design is that the same subject is used for both test and control groups, thereby diminishing the influence of interindividual variability and allowing a smaller sample size. However, important limitations to a crossover design are the assumptions that the effects of the treatment assigned during the first period have no residual effect on the treatment assigned during the second period, and that the patient's condition does not change during the periods being compared.

In a *fixed sample size design*, the trialists specify the necessary sample size before patient recruitment, whereas in an *open or closed sequential design*, subjects are enrolled only if the evolving test-control difference from previous subjects remains within prespecified boundaries.^{15,16} Trials with a fixed design can be configured to continue until the requisite number of endpoints is reached (event driven), thus ensuring that enough endpoints will occur to provide intended power to evaluate the null and alternative hypotheses. When both the patient and the investigator are aware of the treatment assignment, the trial is said to be *unblinded*. *Single-blind* trials mask the treatment from the patient but permit it to be known by the investigator, *double-blind* trials mask the treatment assignment from both the patient and the investigator, and *triple-blind* trials also mask the actual treatment assignment from the DSMB and provide data only in the form of group A and group B categories.

Withdrawal Studies

A *withdrawal study* evaluates the patient's response to discontinuation of treatment or reduction in the intensity of treatment for a cardiovascular condition (see **Fig. 6-3D**). Because patients previously experiencing incapacitating side effects would have been taken off the test intervention, they are not available for withdrawal. This bias toward selection of patients who tolerate a test intervention can overestimate benefit and underestimate toxicity associated with the treatment. In addition, changes in the natural history of the disease in a given patient may influence the response to withdrawal of therapy.

Factorial Design

In a *factorial design*, multiple treatments can be compared with control within a single trial through independent randomizations (**Fig. 6-4**). Because patients with CVD typically receive multiple therapies, the factorial design is more reflective of actual clinical practice than trials in which only a single intervention is randomized. Multiple comparisons can be efficiently performed in a single large factorial design trial that is smaller than the sum of two independent clinical trials. Each intervention should be evaluated individually against control and the possibility of interaction between the factors should be evaluated, because the validity of comparisons within each factor depends on the absence of interaction. Factorial designs may not be appropriate if there is an a priori reason to anticipate interactions (e.g., resulting from related mechanisms of action) (see **Fig. 6-4**).

TABLE 6-3 Trial Designs to Replace Standard of Care

PARAMETER	SUPERIORITY	NONINFERIORITY	
		Objective 1	Objective 2
Goal	Test beats control	Test beats placebo	Test as good as standard
H_0	$P_{\text{test}} = P_{\text{control}}$	Assessment of test made against putative placebo	$P_{\text{test}} \geq P_{\text{standard}} + M$
H_A	$P_{\text{test}} < P_{\text{control}}$		$P_{\text{test}} < P_{\text{standard}} + M$
Source of data	Trial	Historical data	Trial
Type I error	Set by regulatory authorities, typically 0.05	Set by regulatory authorities, typically 0.05	Set by regulatory authorities, typically 0.05
Type II error (power)	Set by investigator	N/A	Set by investigator
Major threats to validity	Assay sensitivity; bias	Assay constancy	Assay sensitivity; bias
Inferential reasoning from trial	Results in study cohort yield estimate of $P_{\text{test}} - P_{\text{control}}$ in population of patients with same clinical characteristics and disease state	Combining results from the trial ($P_{\text{test}} - P_{\text{standard}}$) and historical data ($P_{\text{standard}} - P_{\text{placebo}}$) yields estimate of ($P_{\text{test}} - P_{\text{placebo}}$) in population of patients with same clinical characteristics and disease state	Results in study cohort yield estimate of $P_{\text{test}} - P_{\text{standard}}$ in population of patients with same clinical characteristics and disease state
Generalizability to universe of <i>all</i> patients with the disease state	Related to enrollment criteria; the more restrictive they are, the less generalizable are the results to the entire universe of patients with the disease state	Enrollment criteria of prior trials and medical practice concurrent with those trials determines generalizability of estimate of $P_{\text{standard}} - P_{\text{placebo}}$ to contemporary practice	Related to enrollment criteria; the more restrictive they are, the less generalizable are the results to the entire universe of patients with the disease state

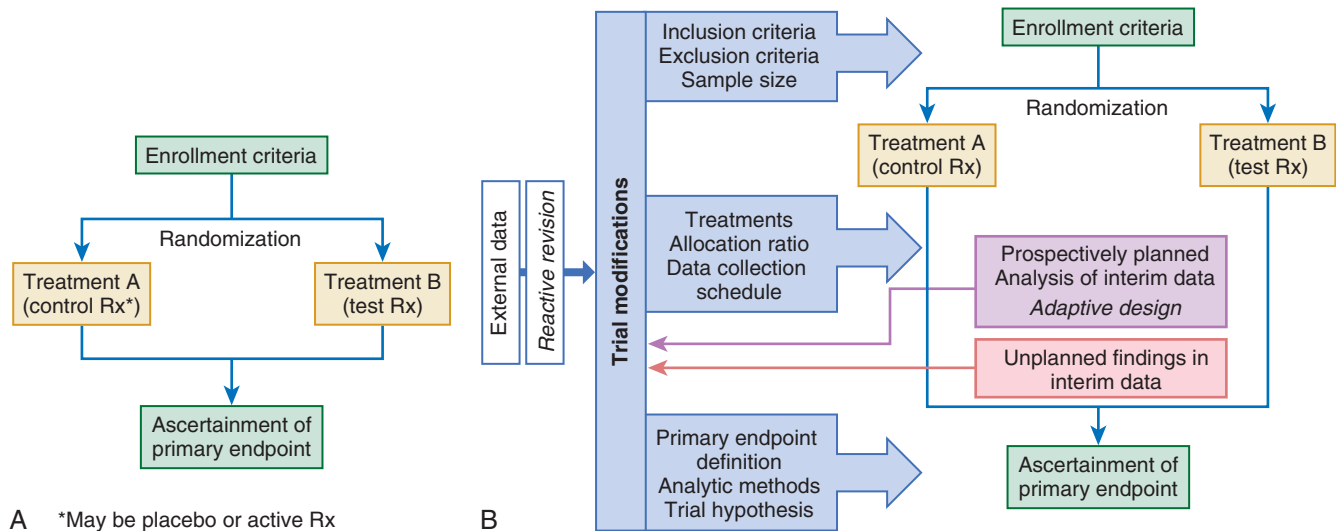

FIGURE 6-2 **A**, Basic structure of a randomized control trial (RCT). The investigators specify the enrollment criteria for the study population. Allocation to the treatment groups occurs through a randomization scheme, subjects are followed, and the primary endpoint is ascertained. **B**, The design of the RCT may be modified at the major levels shown. When the modification is in response to data external to the trial, it is referred to as a reactive revision (*left side*). When the investigators prospectively plan an analysis of interim data for the purposes of modifying the trial, it is referred to as an adaptive design. Unplanned findings in interim data (e.g., data safety monitoring board recommendation) also may provoke a modification of the trial design. (Modified from Antman E, Weiss S, Loscalzo J: *Systems pharmacology, pharmacogenetics, and clinical trial design in network medicine*. Wiley Interdiscip Rev Syst Biol Med 4:367, 2012.)

Selection of Endpoint of Clinical Trial

Evaluation of new treatments in the face of rising costs and reduced mortality rates for cardiovascular illnesses has resulted in two major approaches to the selection of endpoints. The first is to use a composite endpoint with a perceived logical grouping of events, whereby each of the elements of the endpoints is believed to be affected by the treatments being studied. During the course of a trial but before unblinding, investigators may assess the aggregate (all treatment groups combined) event rate for the primary endpoint to ascertain whether the initial estimates of the event rate in the control arm and the anticipated treatment effect of the intervention were reasonable.¹⁶ A low aggregate event rate may reflect inaccuracies in the control rate or treatment effect; investigators may respond by modifying the sample size or expanding the definition of the primary endpoint (see Fig. 6-2B).

Some investigators use a term such as MACE (*major adverse cardiac events*) to refer to the composite endpoint that they selected,

but readers need to evaluate the methods sections in clinical trial reports rigorously, because such phrases may be used differently across trial groups. This situation may improve in the future, as a result of a movement toward standardization of the definitions of endpoints in RCTs.¹⁷ Interpretation of composite endpoints is challenging when the various component elements show different quantitative or qualitative responses to a new treatment. For example, the new treatment may reduce a nonfatal element such as hospitalization for heart failure but may increase total mortality. Efforts to address the complexities of composite endpoints include evaluating the total number of endpoints (first element as well as recurrent nonfatal components) as well as novel weighting schemes using matched pairs of patients in the treatment and control groups to calculate a “win ratio.”^{18,19}

The balance of benefit and risk associated with a new treatment may be described using terms such as *net clinical benefit*, *net clinical outcome*, or *NACE* (*net adverse cardiac events*). Such terms typically

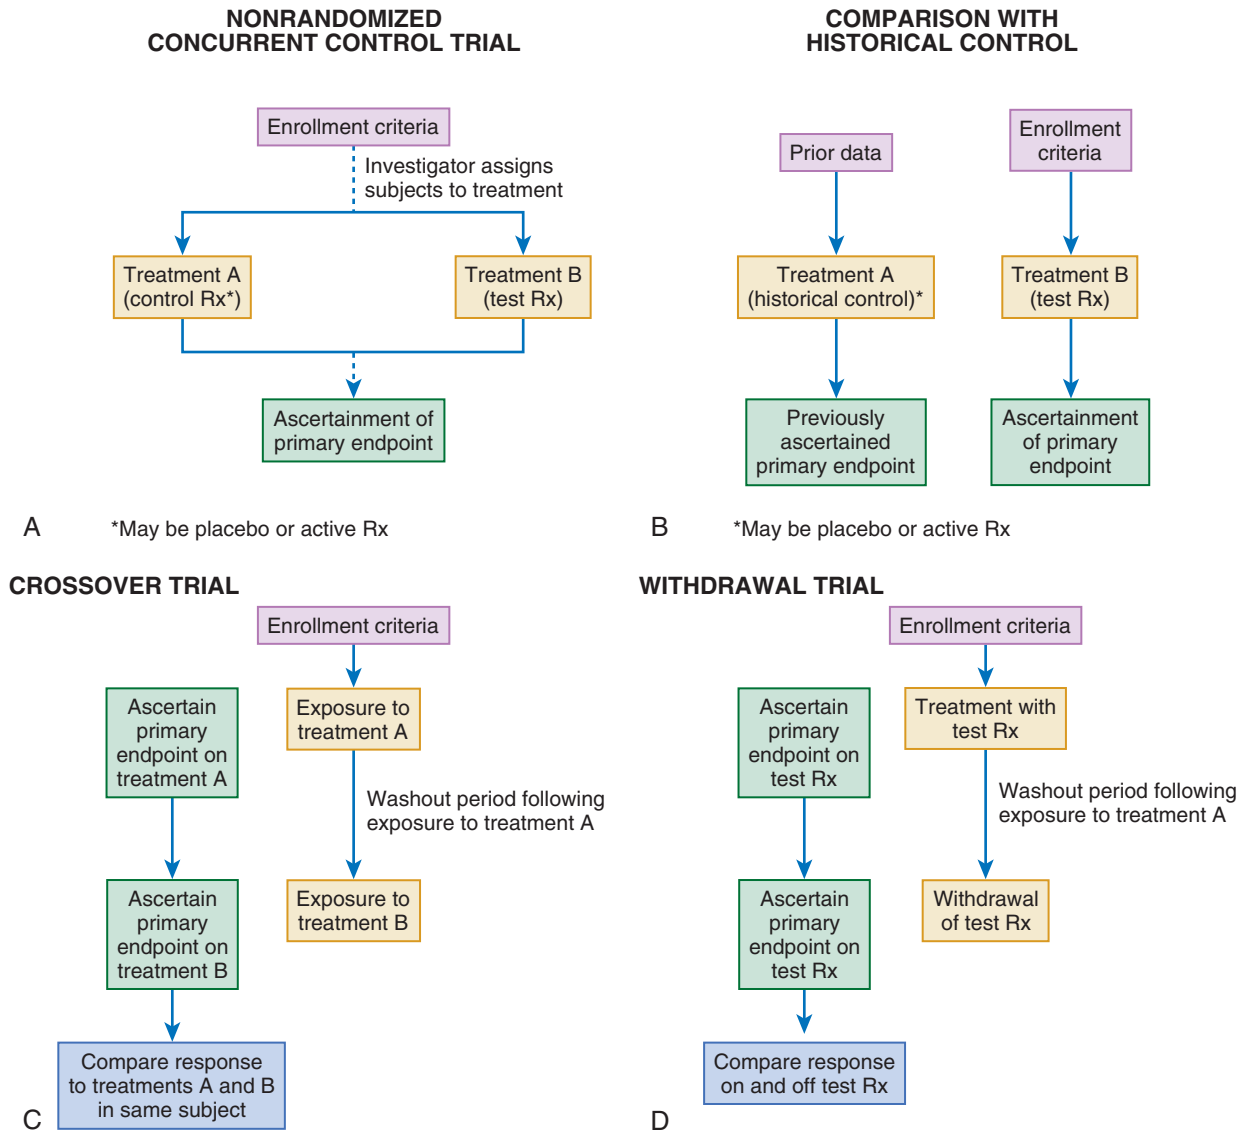

FIGURE 6-3 Other forms of controlled studies. **A**, Features of nonrandomized concurrent control trial. **B**, Design features of a trial using an historical control group. **C**, Design features of a crossover trial. (For an example of this type of trial to evaluate an intervention for angina pectoris, refer to Cole PL, Beamer AD, McGowan N, et al: Efficacy and safety of perhexiline maleate in refractory angina. A double-blind placebo-controlled clinical trial of a novel antianginal agent. *Circulation* 81:1260, 1990.) **D**, Design features of a withdrawal trial. (For an example of the use of this type of trial to evaluate the use of digoxin in patients with chronic heart failure, refer to Packer M, Gheorghade M, Young JB, et al: Withdrawal of digoxin from patients with chronic heart failure treated with angiotensin-converting-enzyme inhibitors. *RADIANCE Study*. *N Engl J Med* 329:1, 1993.)

combine elements of efficacy and safety (e.g., cardiovascular death, nonfatal myocardial infarction [MI], nonfatal stroke, nonfatal major bleed) and provide clinicians with a summary statement about what to expect from a new treatment. Although this is appealing, controversy remains because of a lack of agreement on weighting schemes to interpret composite endpoints, especially when nonfatal safety elements (e.g., bleeding) are combined with efficacy elements (e.g., prevention of MI).

Another approach is to use a surrogate endpoint as a substitute for measuring more traditional clinical outcomes.²⁰ Surrogate endpoints are attractive to investigators because they often are measured on an interval (continuous) scale and can lead to trials with a smaller sample size. However, the field of cardiology is replete with examples of trials configured around surrogate endpoints that not only failed to demonstrate benefit but actually uncovered harm (e.g., increased mortality) associated with a new treatment. Surrogate endpoints are useful if they lie in the causal pathway of a disease and if interventions that affect them are reliably associated with changes in clinical outcomes. **Figure e6-2** illustrates a range of settings in which surrogate endpoints failed to serve as useful substitutes for measuring “hard” clinical events in cardiovascular trials.

KEY ISSUES

During the Course of the Trial

Contemporary trials require surveillance of multiple issues on a regular basis (**Fig. e6-3**). The determination as to whether an event (efficacy, safety) has occurred is the responsibility of a clinical events committee (CEC). Members of a CEC typically are experts in the field, remain blinded to the treatment assignment, and adjudicate events according to a charter established before initiation of enrollment.¹⁷ Because it would not be possible for investigators to maintain equipoise as the events in a trial begin to accumulate, the DSMB assesses the data at prespecified intervals to ascertain whether the accumulating evidence strongly suggests an advantage of one treatment (**Fig. e6-4**).²¹

A critical aspect of a trial that impacts the analysis and interpretation of the findings is missing data. Subjects who initially agree to participation in an RCT may decline to continue to take a blinded study drug at some point during the course of the trial. Rather than ceasing follow-up in such subjects (i.e., censoring the data), trialists should strive to obtain follow-up data by asking subjects who stop taking a study drug to allow the investigators to obtain follow-up on

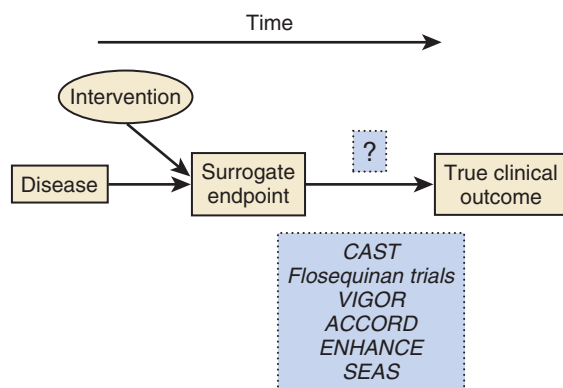

FIGURE e6-2 Surrogate endpoints. Selection of a surrogate endpoint in a clinical trial provides reliable information for clinicians if the surrogate endpoint is in the causal pathway of the disease with respect to clinical outcomes and the intervention acts on the surrogate endpoint so as to truly affect clinical outcome. Some examples of trials in cardiovascular medicine for which this paradigm failed are CAST (Cardiac Arrhythmia Suppressor Trial); studies of flosequinan; VIGOR (Vioxx GI Outcomes Research); ACCORD (Action to Control Cardiovascular Risk in Diabetes); ENHANCE (Ezetimibe and Simvastatin in Hypercholesterolemia Enhances Atherosclerosis Regression); and SEAS (Simvastatin and Ezetimibe in Aortic Stenosis). (Modified from Fleming TR, DeMets DL: *Surrogate end points in clinical trials: Are we being misled?* *Ann Intern Med* 125:605, 1996.)

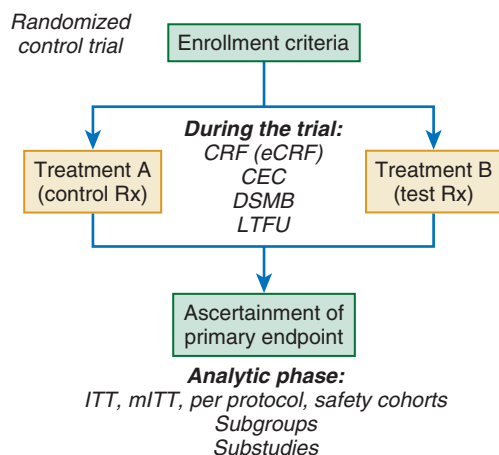

FIGURE e6-3 Conduct during recruitment and follow-up of subjects in the trial and during the analytic phase. The case report form (CRF) is an important barometer of the quality of the data being collected at investigative sites. Surveillance procedures need to be in place for central review of the data being submitted to trap for key items such as any violations of the enrollment criteria, range check errors (e.g., number of digits or units for age, weight, biomarkers, etc.), adequacy of the information being submitted for suspected endpoint events, and timely submission of adverse events (a regulatory reporting responsibility). Many of these tasks are facilitated by the use of an electronic CRF (eCRF) that can be completed using an Internet-based interface. The complexity of monitoring the tasks may be handled by a contract research organization (CRO) that has a large staff capable of visiting the enrolling sites. Additional quality checks that typically are conducted by a CRO include source document verification (inspection of primary medical record) for suspected endpoint events and random sampling of subjects who did not experience any events. Retention of subjects in the trial and minimizing loss to follow-up (LTFU) also are key quality measures. CEC = clinical events committee; DSMB = data safety monitoring board; ITT = intention to treat; mITT = modified intention to treat.

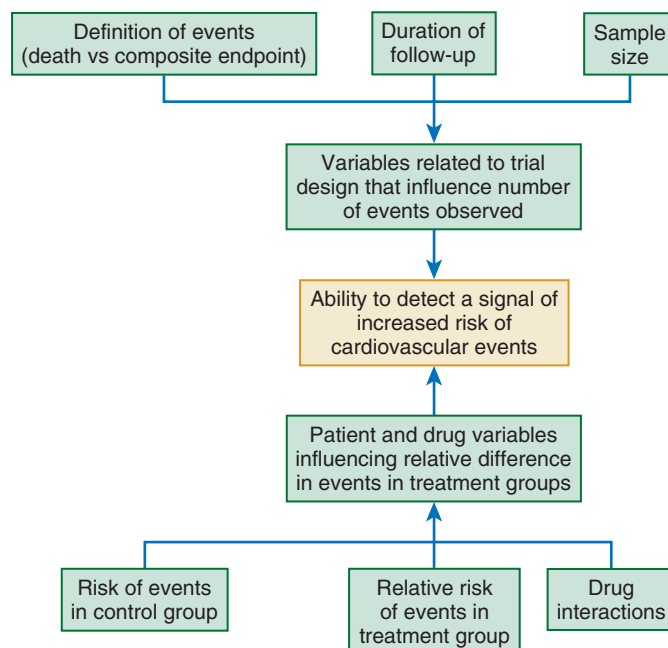

FIGURE e6-4 Detection of treatment effects in clinical trials. Factors related to trial design (top) and to the patient and drug being investigated (bottom) are shown. The interplay of these factors influences the ability to detect a treatment effect in a clinical trial. (Reproduced with permission from Antman EM, DeMets D, Loscalzo J: *Cyclooxygenase inhibition and cardiovascular risk.* *Circulation* 112:759, 2005.)

them either through office visits, telephone contact, or review of their medical records.^{22,23} Every effort also should be made to track patients who move during the course of the trial to avoid “loss to follow-up.”²³

Stopping boundaries to guide the DSMB are usually agreed on before the initiation of enrollment. Such stopping boundaries need to take into account the uncertainty of the evidence at iterative interim looks at the data and the play of chance, which may produce a situation in which one treatment appears to be favorable. During these interim looks at the data, members of the DSMB inspect the differences between treatment groups expressed as a standardized normal statistic (Z_i). Usually, Z_i plots depict evidence of superiority of the test treatment in the upward (positive) direction and inferiority of the test treatment in the downward direction.²¹

Stopping boundaries may be symmetric (Fig. 6-5) or asymmetric. Investigators and DSMB members may agree to use an asymmetric stopping boundary scheme that requires less compelling evidence to cross a lower bound for inferiority of a new treatment when an acceptable standard treatment is clinically available and the new treatment is associated with safety concerns (e.g., intracranial hemorrhage during the evaluation of a new fibrinolytic). The DSMB may also be called on to determine whether a particular dose group

	Active A 5000	Placebo A 5000
Active B 5000	Active A Active B 2500	Placebo A Active B 2500
Placebo B 5000	Active A Placebo B 2500	Placebo A Placebo B 2500

Total enrollment = 10,000 patients

Evaluation of drug A alone and in combination with drug B:

Active A/Placebo B vs Placebo A/Placebo B = Difference₁ = D_1

Active A/Active B vs Placebo A/Active B = Difference₂ = D_2

Treatment effect of drug A in the absence of drug B = D_1

Treatment effect of drug A in the presence of drug B = D_2

Grand summary of treatment effect of drug A = $D_1 + D_2$

Effect of drug B on treatment effect of drug A = $D_2 - D_1$

FIGURE 6-4 Factorial design of clinical trial. In this example, 10,000 patients are randomized to receive or not receive two interventions (drug A and drug B). Each patient will fall into one of the following four categories: Active A/Active B, Placebo A/Active B, Active A/Placebo B, Placebo A/Placebo B. Definitions/equations at bottom: Differences in event rates for the comparisons permit an assessment of the treatment effect of drug A in the presence and absence of drug B. See text for further discussion. (From Antman E: *Medical therapy for acute coronary syndromes: an overview*. In Califf R, Braunwald E [eds]: *Acute Myocardial Infarction and Other Acute Ischemic Syndromes*. Philadelphia, Current Medicine, 1996, pp 10.1-10.25.)

should be discontinued (adaptive design) (see Fig. 6-2B) and whether the trial is futile (e.g., that conditional on the data accumulated at the i -th look, there is only a 10% chance that H_0 would be rejected at the end of the trial).

During the Analytic Phase of the Trial

Before unblinding the results of the trial (i.e., revealing patient outcomes by treatment group to the investigators), investigators should have finalized a statistical analysis plan (SAP). Key features of the SAP include a definition of the cohorts of trial subjects to be analyzed (Table 6-4), the statistical test(s) to be used to analyze the primary endpoint (e.g., for comparison of proportions or time to event), conventions for handling missing data,^{22,24} time windows for analyzing data (e.g., randomization through common study end date), and

FIGURE 6-5 Sequential stopping boundaries used in monitoring a clinical trial. Shown are three sequential stopping boundaries for the standardized normal statistic (Z_i) for up to five sequential groups (of patients enrolled in the trial by the i -th analysis), with a final two-sided significance level of 0.05. (From Friedman LM, Furberg CD, DeMets DL: *Fundamentals of Clinical Trials*. 4th ed. New York, Springer Verlag, 1998.)

TABLE 6-4 Examples of Definitions of Analytic Cohorts in a Clinical Trial

ANALYTIC COHORT	REFERENCE DATE	EXCLUDE IF PROTOCOL VIOLATIONS DISCOVERED	REQUIRE THAT SUBJECT RECEIVED AT LEAST ONE DOSE OF STUDY DRUG	TREATMENT ASSIGNMENT FOR ANALYTIC PURPOSES
Intention to treat	Randomization	No	No	As per randomization
Modified intention to treat	May start at initial dose of study drug	No (may vary)	May introduce this requirement	As per randomization
Per protocol	Initial dose of study drug	Yes	Yes	Usually as per randomization, but sensitivity analyses that account for actual treatment received may be performed
Safety	Usually at time of initial dose of study drug	No	Yes	Usually as per actual treatment received, but sensitivity analyses that use treatment assigned at randomization may be performed

FIGURE 6-6 Probability that multiple subgroup analyses will yield at least one (red line), two (blue line), or three (yellow line) false-positive results. (From Lagakos SW: *The challenge of subgroup analyses—reporting without distorting*. *N Engl J Med* 354:1667, 2006.)

subgroups of interest (see Fig. e6-3). Depending on the exact definitions used for the analytic cohorts (see Table 6-4), the denominators may vary; this may lead to slight variations in the estimates of event rates and treatment effects. Ideally, the main results of the trial will be similar in the intention to treatment and per protocol cohorts. If they are not, an explanation should be sought from additional analyses of the data.

Missing data present a serious challenge to analysis of trial results. Depending on the mechanism leading to the missing data, the information is considered in one of three categories: (1) missing completely at random, where “missingness” is unrelated to the study (e.g., flood destroys case report forms); (2) missing at random, where the characteristics of the subject can account for differences in the distribution of missing data (e.g., elderly subjects have more missing visits than younger subjects); and (3) missing not at random, where “missingness” depends on the value of the missing observation. The last category is especially problematic because it is likely to be informative and nonignorable—for example, subjects assigned to the test intervention are more likely to have side effects and drop out of the study.²² Biostatisticians advise against using simple adjustment methods for dealing with missing data (e.g., analyzing only subjects who complete the trial, or a single imputation such as carrying the last observation forward). They recommend, instead, using statistical models based on the data and performing sensitivity analyses to examine the robustness of the trial findings.²²

Not all patients will respond to a given treatment in a clinical trial to the same extent. The role of pharmacogenomics in determining the response to therapeutic agents is discussed in Chapter 9. Because not all patients will respond to a given treatment, it is of clinical interest to inspect the data stratified by subgroups of interest.²⁵ Although such an approach initially may seem appealing, a number of considerations limit the investigator’s ability to draw conclusions from subgroup analyses. Typically, subgroups involve univariate analyses of the data (e.g., men versus women) but the clinical picture is more complex, such that an individual patient will belong to multiple subgroups. Responses in subgroups should be evaluated by an interaction test, which determines whether the relative efficacy of treatments differs among the subgroups being examined. A *quantitative* interaction is said to be present when the treatment effect varies in magnitude but not in direction across subgroups.²⁵ A *qualitative* interaction is said to be present when the direction of the treatment effect varies among the subgroups.²⁵ Note that a qualitative interaction also must be a quantitative interaction. Of importance, the multiplicity of subgroup analyses inflates the false-positive rate

(Fig. 6-6). Rather than relying on a *P* value for a subgroup response, investigators and readers should focus on a graphic display of subgroup data depicting the point estimates and confidence intervals for the treatment effect. Such an approach provides a summary of the range of plausible treatment effects observed in a trial.

MEASURES AND DETECTION OF TREATMENT EFFECT

Events in a clinical trial may be measured on a nominal (dichotomous), categorical, or interval (continuous) scale.²⁶ Clinical trials reports should use descriptive statistics, graphic displays, and estimates of the precision of the observations appropriate for the scale of measurement being used in the trial.²⁶ A common assessment in a cardiovascular trial is comparison of the proportions of patients experiencing a dichotomous event (e.g., dead versus alive) during the follow-up period of the trial. When the outcome is an undesirable cardiovascular response and the data are arranged as investigational group compared with control group, a *relative risk* (RR) or *odds ratio* (OR) of less than 1 indicates benefit of the investigational treatment (see Fig. 6-1).

Interpretation of the treatment effect should take into account the absolute risk of the outcomes. The *absolute risk difference* (ARD) is the difference in events in the treatment group and the control group and is particularly useful when expressed as the number of patients that must be treated ($N = 1/\text{ARD}$), or *number needed to treat* (NNT), to observe the beneficial effect in one patient. Similarly, the absolute risk increase (ARI) in adverse events with the investigational treatment can be converted into the *number needed to harm* (NNH). By comparing the NNT and NNH for a given treatment, clinicians can assess the risk-benefit balance and also benchmark the treatment effects of the new therapy against other treatments used in contemporary cardiovascular practice. Another useful metric is to express the outcome for every 1000 patients treated.

The NNT (or NNH) should be interpreted in the context of the time frame of the trial. For example, in patients with an acute coronary syndrome (ACS) undergoing percutaneous coronary intervention (PCI), use of prasugrel instead of clopidogrel over 14.5 months is associated with an NNT of 46 (to prevent one event of CV death, MI, or stroke) and NNH of 167 (to cause one excess major bleed) (see Chapter 55).²⁷ Use of rosuvastatin (versus placebo) in apparently healthy persons with a low-density lipoprotein cholesterol less than 130 mg/dL but elevated C-reactive protein level is associated with a 5-year NNT value of 20 (to prevent one event of MI, stroke, revascularization, or death) (see Chapter 42).²⁸ In some therapies, the balance of NNT and NNH is even more complex, because a treatment may have an early hazard (e.g., cardiac surgery versus PCI) but be more effective over time²⁹; the balance of NNT and NNH also may vary according to the baseline risk at the time of randomization.³⁰

The interplay of variables set by investigators during the design of a clinical trial, the characteristics of the patients studied, and the features of the treatment being investigated influence the relative difference in events in the treatment groups (see Fig. e6-4). The interface of the patient and the treatment may change over the course of exposure to the treatment (e.g., lower risk of events over time as the patient moves from the acute to chronic phases of a disease), and background therapy also may change during the course of the trial (e.g., with treatments added or removed or doses modified). Although these considerations can influence the likelihood of a “positive” trial, they also have an impact on the ability to detect a signal of harm (Fig. e6-5).

FUTURE PERSPECTIVES

Trialists, peer reviewers, and journal editors now have checklists and templates that codify the reporting of clinical trials (Table e6-1).

FIGURE e6-5 Number needed to harm. The relationship of the event rate in the control group and the relative risk of cardiovascular events with the treatment being investigated determines the number of patients who need to be treated with the drug to observe one cardiovascular event (number needed to harm). The surface generated can be used to understand the relative ease or difficulty of detecting a signal of harm with a particular treatment (e.g., cyclooxygenase inhibition). (Reproduced with permission from Antman EM, DeMets D, Loscalzo J: Cyclooxygenase inhibition and cardiovascular risk. *Circulation* 112:759, 2005.)

TABLE e6-1 Checklist of Information for Inclusion in Reports of Clinical Trials

Introduction
Clear statement of a priori hypothesis and specific research objective(s)
Methods
Study as designed; include: <ol style="list-style-type: none"> 1. Planned study population, including controls 2. Inclusion and exclusion criteria 3. Planned subgroup analyses 4. Prognostic factors that may affect study results 5. Outcome measures and minimum difference(s) to be considered clinically important 6. Planned treatment interventions 7. Method of assignment of subjects to treatments (for example, randomization method, stratification blinding or masking procedure, matching criteria) 8. Planned sample size, power calculations 9. Use of data safety and monitoring board and rules for stopping the study 10. Methods of statistical analysis in sufficient detail to permit replication
Results
Study as conducted; include: <ol style="list-style-type: none"> 1. Inclusive dates of accrual of study population 2. Sample size achieved 3. Report of extent of follow-up 4. How many subjects were excluded or withdrew and the reasons 5. Demographics and clinical characteristics of the study population, including controls 6. How the study as conducted deviated from the study as planned and the reasons (for example, compliance) Study findings; include: <ol style="list-style-type: none"> 1. Cohorts analyzed (e.g., intention to treat) 2. Estimates of treatment effects, stated as comparisons among treatment groups (for example, differences in risks, rates, or means of outcome measures, as well as exact <i>P</i> values, not just <i>P</i> < 0.05) 3. Measures of precision for outcome measures and for estimates of treatment effects (e.g., confidence intervals) 4. Summary data and appropriate descriptive statistics 5. Complications of treatment 6. Repository where original data can be obtained
Discussion
Interpretation of study finding
Results considered in the context of results in other trials reported in the literature

Modified from Working Group on Recommendations for Reporting of Clinical Trials in Biomedical Literature: Call for comments on a proposal to improve reporting of clinical trials in the biomedical literature. *Ann Int Med* 121:894, 1994; Stanley K: Evaluation of randomized controlled trials. *Circulation* 115:1819, 2007.

TABLE 6-5 Questions to Ask When Reading and Interpreting the Results of a Clinical Trial

Are the Results of the Study Valid?
Primary Guides
1. Was the assignment of patients to treatment randomized? 2. Were all patients who entered the trial properly accounted for and attributed at its conclusion? a. Was follow-up complete? b. Were patients analyzed in the groups to which they were randomized?
Secondary Guides
1. Were patients, their clinicians, and study personnel “blind” to treatment? a. Were the groups similar at the start of the trial? b. Aside from the experimental intervention, were the groups treated equally?
What Were the Results?
1. How large was the treatment effect? 2. How precise was the treatment effect?
Will the Results Help Me in Caring for My Patients?
1. Does my patient fulfill the enrollment criteria for the trial? If not, how close is my patient to the enrollment criteria? 2. Does my patient fit the features of a subgroup in the trial report? If so, are the results of the subgroup analysis in the trial valid? 3. Were all the clinically important outcomes considered? 4. Were important concomitant treatments described? 5. Are the likely treatment benefits worth the potential harm and costs?

Modified from material in Guyatt GH, Sackett DL, Cook DJ: *The medical literature: Users' guides to the medical literature: II. How to use an article about therapy or prevention: A. Are the results of the study valid?* JAMA 270:2598, 1993; Guyatt GH, Sackett DL, Cook DJ: *The medical literature: Users' guides to the medical literature: II. How to use an article about therapy or prevention: B. What were the results and will they help me in caring for my patients?* JAMA 271:59, 1994; and Stanley K: *Evaluation of randomized controlled trials.* Circulation 115:1819, 2007.

Clinicians can refer to guides for reading and interpreting clinical trials (Table 6-5).³¹ These advances, however, deal only with clinical trials that reach the point at which they are reported in a publicly available format. Considerable concern has been expressed in the past that some clinical trials, especially those with negative results, were never reported. The introduction of a requirement to register clinical trials in an online repository (e.g., www.clinicaltrials.gov) was an important step forward, but specific details typically are limited on such postings. Current requirements that clinical trials post a final study report within a reasonable period after study completion (1 year) will assist those investigators planning future trials, clinicians seeking the latest information about treatments, and writing committees charged with creating guidelines documents who need up-to-date and complete data to formulate recommendations. The full impact of this requirement has not yet been realized, however.³²

Additional directions for RCTs in the future include (1) involving patients in structuring research questions assessing the value of health care options,³³ (2) engaging community representatives in the

planning of trials (community-based participatory research),³⁴ and (3) using a patient's electronic medical record to embed randomization between treatment options.^{3,4}

REFERENCES, 62

April 14, 2013 marked the 10th anniversary of the completion of the Human Genome Project. In just 10 years the field of genomics—the scientific study of genomes, their complete DNA sequences, and the functional interaction of their genes—has flourished as a result of high throughput technologies to generate, analyze, and interpret genome-derived data efficiently and cost-effectively. A broad aspiration of the Human Genome Project has been the concept of *personalized medicine*—a rapidly advancing field of health care that is informed by a person's unique clinical, genetic, genomic, and environmental information.¹ Personalized medicine seeks to couple established clinical-pathologic indices with state-of-the-art molecular profiling to create diagnostic, prognostic, and therapeutic strategies precisely tailored to each patient's requirements—hence the term *precision medicine*. Although this concept is not entirely new, many patients and providers have had great expectations that the genome would enable the development of novel diagnostic and predictive tests as well as therapies based on an individual's genetic information. This chapter presents a broad overview of the potential of personalized medicine. Subsequent chapters (**Chapters 8 to 10, and 42**) will elaborate specific approaches to various aspects of personalized medicine.

This decade also marks the 50th anniversary of the introduction of the term “factor of risk,” coined by William Kannel, principal investigator of the Framingham Heart Study (FHS).² The risk factors for developing coronary artery disease (CAD)—male sex, hypertension, diabetes mellitus, increased low-density lipoprotein (LDL) cholesterol, tobacco use, and family history of heart disease—remain foundational for stratifying individuals to therapeutic strategies based on their risk of developing CAD. The FHS was among the first studies to illustrate the benefit of data integration to achieve refined risk classification. The massive and comprehensive collection of clinical and biologic data associated with the outcome of coronary disease enabled development of the Framingham predictive models³ and the

resulting Framingham risk score (FRS).⁴ Today, it is anticipated that the inclusion of data that address the subtle distinctions in individuals revealed through genomic analyses might greatly enhance this prediction—a concept that has stimulated the development of genomic risk scores (GRSs) combined with the FRS (see later in this chapter) to enhance predictive accuracy. The opportunity for impact on clinical decision making offered by genome technologies lies in increased resolution: the potential to improve a person's placement on the complex, multidimensional risk spectrum based on detailed, individual molecular characteristics on a genomic scale. The FHS example emphasizes the value of making use of the full spectrum of available clinical and demographic data; the genomic era simply expands this view toward integrated approaches that embrace and exploit genomic data in conjunction with other data.

ASSESSMENT OF DISEASE RISK: FAMILY HEALTH HISTORY AND HEALTH RISK ASSESSMENTS

Several approaches to risk assessment for cardiovascular disease have emerged that, if routinely used, might impact our ability to tailor chronic disease prevention strategies to the individual and promote improved cardiovascular public health. These include the FRS,⁴ the Reynolds risk score,⁵ and the European Society of Cardiology score.⁶ My colleague and I proposed a framework that includes family history assessment to identify high-risk persons for disease, thus enabling preventive and therapeutic interventions.⁷ Family health history (FHH) is a simple yet invaluable tool for the delivery of personal health risk information. Reflecting the complex combination of shared genetic, environmental, and lifestyle factors, a thorough FHH can approximate genetic/genomic risk information for integration

into patient care. FHH assessments can identify persons at higher risk for common chronic diseases, enabling preemptive and preventive steps including lifestyle changes, health screenings, testing, and early treatment as appropriate.

Systematic collection of FHH for cardiovascular risk assessment was recently implemented in 24 family practices in the United Kingdom using a pragmatic cluster randomized controlled trial design, and demonstrated a highly significant (40%) increase in the identification of individuals at high risk.⁸ This was the first rigorously designed prospective study to show that the collection and use of FHH in a primary care setting can improve risk stratification for cardiovascular disease and health behaviors. Thus, ascertainment of FHH data is a feasible practice-level intervention that could improve cardiovascular risk assessment and help target patients who most need preventive interventions.

Family history and genomic testing are complementary techniques for evaluating health risks.⁹ Rather than choosing between the two, an approach that incorporates both types of information, in addition to nongenetic risk factors, promises the most accuracy. The combination of detailed family history, medical history, clinical evaluation, and genome sequence information, as exemplified by the ClinSeq Project at the National Human Genome Research Institute (NHGRI),¹⁰ may eventually provide the most accurate cardiac risk prediction.

A GENOMIC TOOLBOX FOR PERSONALIZED AND PRECISION MEDICINE

Several genome-wide technology platforms are now routinely available for the exploration of the impact of the genome and its expressed products on health and disease states (see also Chapter 8). Concurrently, several cohort studies with longitudinal clinical data and biologic specimens sponsored by the National Heart, Lung, and Blood Institute (NHLBI) provide the opportunity for molecular analyses, disease classification, and predictive modeling. These include the FHS, the Coronary Artery Risk Development in Young Adults (CARDIA) study, the Atherosclerosis Risk in Communities (ARIC) study, the Jackson Heart Study (JHS), the Women's Health Initiative (WHI) study, the Cardiovascular Health Study (CHS), and the Multi-Ethnic Study of Atherosclerosis (MESA). These powerful longitudinal studies and their clinical data and biospecimens can be accessed via the NHLBI's BioLINCC program (<https://biolincc.nhlbi.nih.gov>), which contains a vast catalog of biospecimens resources that can be used to facilitate population genomics, using the tools outlined below. The discovery and development of genome-based biomarkers requires high-quality biospecimens linked to exquisitely defined phenotypes, assayed using one or more genome-based technologies. Their translation to clinical application forms the basis for personalized medical care.

DNA Variation

Genome-wide association studies (GWASs) emerged in 2005 as an unbiased strategy to provide information on common DNA variants associated with complex phenotypes. GWASs are predicated on the common disease–common variant hypothesis, which postulates that common diseases result from many disease-influencing alleles that occur at relatively high frequencies in the population, but individually have little predictive value. Nineteen published GWASs on CAD are recorded in the NHGRI Catalogue of GWASs (<http://www.genome.gov/26525384>), the largest being a meta-analysis of 63,746 CAD cases and 130,681 control cases.¹¹ The total number of loci for CAD now exceeds 46. These loci encompass genes related to lipid metabolism and other CAD risk factors, but some novel loci—such as the region on chromosome 9 near the genes *CDKN2A/CDKN2B*—represent truly novel risk variants that will advance our understanding of the mechanisms underlying CAD. Together, these variants account for less than 10% of the heritability of CAD, suggesting the involvement of genetic factors beyond common variants.

Whole-Genome Sequencing

Advances in sequencing technologies have reduced costs such that a human genome can now be sequenced for less than \$5000, and may be at the \$1000 level in the coming year.¹² At this cost, sequencing a patient's genome will fall within the range of DNA-based diagnostic tests. More than 30,000 human genomes¹³ have now been sequenced and applied to elucidation of the biology and diagnosis of malignancies, rare genetic diseases, and microbial infections.^{14–16} Whole-genome sequencing also has advanced to the clinic, where it permits definitive diagnosis and even guides treatment.^{17–19} Although these approaches have yielded success when applied to mendelian disorders and cancer, methods for identifying rare variants for common diseases such as CAD are still nascent.²⁰

GENE EXPRESSION

The genome-wide study of RNA expression levels includes a spectrum of molecules from mRNA to noncoding RNAs. Microarrays and RNA sequencing now can assay the entire complement of RNA expressed in a cell, tissue, or biologic fluid. Clustering of co-expressed genes using parametric or nonparametric methods provides the foundation for generating a “pattern” or “signature” of gene expression that is associated with a phenotype or physiologic state. These methods have been applied to classify a disease or to predict future disease states; the same data may also serve to generate molecular pathway information for the biologic mechanisms underlying disease. Two recent reviews nicely summarize the emerging gene expression–derived biomarkers for clinical applications in cardiovascular medicine.^{21,22}

A surprising feature of the transcriptome is the significance of noncoding RNAs in the regulation of genes. Of particular interest are the expression patterns of small interfering RNAs (siRNAs) and microRNAs (miRNAs). Whereas siRNAs interfere with transcription through degradation of the message RNA, miRNAs work differently. The latter are usually 22 nucleotides in length, and through an miRNA-induced silencing complex, they inhibit gene expression on a post-transcriptional level by binding to complementary 3' untranslated regions (UTRs) of target mRNA.²³ The miRNAs play a role in several diseases and are advancing to clinical application in acute coronary syndromes,²⁴ acute myocardial infarction (MI),²⁵ cardiomyopathies,²⁶ type 2 diabetes,²⁷ hypertension,²⁸ and heart failure.²⁹ Most of these studies are small and require validation in larger populations.

Proteomics

Proteomics refers to the large-scale study of proteins, and the proteome often is considered to embody the full complement of proteins and their various derivatives (e.g., splice variants or post-translational modification) (see also Chapter 10). In the context of health and disease, proteomics seeks to define the full set of proteins associated with a particular physiologic state. Although this technology is relatively immature in its applications to human health and disease compared with RNA and metabolic profiling, application of these methods, combined with the development of mass spectroscopy technology, should advance proteomics to more routine use in disease classification and diagnosis, prognosis, and pharmacogenomics within the next several years.

Metabolomics

Metabolomics measures the approximately 5000 discrete small molecule metabolites and allows the identification of metabolic fingerprints for specific diseases. This technology may have practical use in the development of therapies, because metabolic changes immediately suggest enzymatic drug targets (see also Chapter 10). Similar to genomics and proteomics, metabolomics may be useful in disease diagnosis, prognosis, and drug development. Targeted

mass spectroscopy-based metabolic profiling has been applied to cardiovascular disease to classify CAD and to predict ischemic events.^{30,31}

PERSONALIZED AND PRECISION CARDIOVASCULAR MEDICINE: CLINICAL POTENTIAL

Hypertension

Genetic variants associated with blood pressure (BP) that robustly replicate have finally emerged from GWASs. The single-nucleotide polymorphisms (SNPs) discovered have mainly been common variants (minor allele frequency [MAF] of $\geq 5\%$), with small effect sizes (mostly ≤ 1 mm Hg for systolic BP [SBP] and ≤ 0.5 mm Hg for diastolic BP [DBP]), and they collectively have explained only a small proportion (3% to 4%) of BP heritability. A recent GWAS investigated associations with SBP, DBP, mean arterial pressure (MAP), and pulse pressure (PP) by genotyping some 50,000 SNPs that capture variation in approximately 2100 candidate genes for cardiovascular phenotypes in 61,619 persons of European ancestry from cohort studies in the United States and Europe. Novel associations were identified for SBP (chromosomal locus 3p25.3 in an intron of *HRH1*; and 11p15 in an intron of *SOX6*, previously associated with MAP) and for DBP (1q32.1 in an intron of *MDM4*). Ten previously known loci associated with SBP, DBP, MAP, or PP were confirmed (*ADRB1*, *ATP2B1*, *SH2B3/ATXN2*, *CSK*, *CYP17A1*, *FURIN*, *HFE*, *LSP1*, *MTHFR*, *SOX6*; $P < 2.4 \times 10^{-6}$).³² These results represent a major advance in view of the fact that just a few years ago, almost no specific details were known about the genetic architecture of hypertension beyond the mendelian disorders. The results of ongoing fine-mapping studies of BP loci and sequence-based discovery of rare variants in extreme hypertensive cases and normotensive controls will provide further insights into the underlying genetic causes of BP, with the potential for improvement in the means for predicting and stratifying hypertension.

Coronary Artery Disease and Myocardial Infarction

As indicated previously, recent studies have identified a growing number of CAD-related and MI-related SNPs, and their results have stimulated additional studies to explore the value of these SNPs for risk prediction. Paynter and associates assessed the relationship of 101 SNPs to CAD in a cohort of 19,000 women, followed for 12 years, from the Women's Genome Health Study.³³ A GRS based on these 101 SNPs revealed a significant relationship between higher GRS and CAD, but failed to add incremental value to existing clinical models. Another GRS based on the counting of the number of "adverse" alleles influencing lipids has been shown to enhance risk prediction compared with measurement of lipids alone.³⁴ Clinical adoption of GRS for CAD risk prediction will require unequivocal evidence that genotype predicts CAD, even after adjustment for plasma lipids and other known CAD risk factors.

Accompanying the transformative discoveries on genetic susceptibility variants just described are additional predictive CAD and MI biomarkers emerging from the expressed genome. Rosenberg and colleagues found that the gene expression signature of 23 genes obtained from the peripheral blood of nondiabetic patients undergoing coronary angiography for acute chest pain permitted reclassification of the risk of having CAD, at a rate of approximately 20% of that for traditional clinical models.³⁵ The negative predictive value of 83% for the gene expression assay compared favorably with typically used clinical tests such as myocardial perfusion imaging. In addition, Voora and co-workers recently reported the development of an RNA signature associated with the platelet response to aspirin and the ability of that same signature to predict acute coronary syndromes in two cohorts.³⁶

Heart Failure

Increasingly detailed characterization of gene expression from diseased tissues and circulating cells from animals and patients are providing new insights into the pathophysiology of heart failure (HF) that permit identification of novel diagnostic and therapeutic targets. Differential gene expression profiles for failing and nonfailing hearts have already identified types of HF with different causes.³⁷ Gene expression profiles usually compare matched pairs of samples, such as nonfailing versus failing hearts, ischemic versus nonischemic hearts, male versus female failing hearts, or atria versus ventricles of failing hearts. This approach identified cardiac myosin light chain kinase (*MLCK*) as an HF-related gene by correlating expression levels with the severity of HF; further investigations confirmed the importance of cardiac *MLCK* in HF. A robust gene expression signature composed of 27 genes emerged from analysis of four independent microarray data sets from evaluation of the failing myocardium of dilated cardiomyopathy.³⁸ Among these genes are several associated with mitochondrial dysfunction and oxidative phosphorylation, as well as three extracellular molecules, including periostin, pleiotrophin, and *SERPINA3*—some of which may become novel diagnostic and therapeutic targets for HF. Although the complexity of genomic and transcriptional profiling may be challenging to use in the clinic, advances in clinical information technology and user interfaces (see were later in this chapter) should permit greater individualization of prevention and treatment strategies to personalize the treatment of HF.³⁹

Arrhythmias

Inherited arrhythmia syndromes and forms of structural heart disease cause arrhythmias and sudden cardiac death (see also Chapters 9 and 33). Genetic testing for these conditions is among the most clinically advanced areas of personalized and precision cardiovascular medicine. Tests for several arrhythmia syndromes are currently available through qualified laboratories including Correlagen, Family/Transgenomic, GeneDx, and Partners Healthcare. A definitive genetic diagnosis for the cause of a rhythm disorder may help to direct clinical recommendations, which include periodic follow-up, avoiding medications that may exacerbate the condition, and avoiding strenuous activities such as competitive sports. In addition, specific genetic diagnoses may guide therapies, such as the use of beta blockers in long-QT syndrome and recommendations for an implantable cardioverter-defibrillator.

Current clinical practice guidelines recommend screening of asymptomatic first-degree relatives and all potentially symptomatic relatives of patients with a known inherited arrhythmia. Identification of a causative gene in a proband should prompt genetic screening of family members, although insurance carriers may not reimburse for the genetic screening of asymptomatic patients. The greatest use for genetic testing at present lies in the ability to define, in a family with an inherited condition of known genetic etiology, unaffected persons who therefore require no further clinical follow-up and cannot pass the condition to their children.

Cardiac Transplant Rejection

Profiling of patients after cardiac transplantation is altering clinical decision making and management of allograft rejection. Standard protocols after heart transplantation require patients to undergo serial endomyocardial biopsies as a means to monitor rejection and to guide immunosuppressive therapy. Horwitz and associates demonstrated that gene expression profiles of peripheral blood mononuclear cells (PBMCs) might provide an alternative approach to the diagnosis of allograft rejection.⁴⁰ Patients who subsequently developed acute rejection had a distinct genomic profile compared with patients without any rejection, and after treatment for rejection, a majority (98%) of differentially expressed genes returned to baseline. The CARGO (Cardiac Allograft Rejection Gene Expression Observational) study prospectively investigated gene expression analysis

from PBMCs as a diagnostic tool to predict transplant rejection.⁴¹ From the core group of 11 genes associated with immune response pathways, which were identified by quantitative real-time polymerase chain reaction (RT-PCR) and assigned weighted scores, the CARGO investigators were able to predict rejection with a sensitivity and specificity of 80% and 60%, respectively.⁴² This study provided proof-of-concept that expression profiling of 11 genes in PBMCs could predict acute rejection pathways in cardiac transplant recipients. One important implication is that blood genomic profiling can provide a sensitive marker for transplant rejection,⁴¹ potentially guiding surveillance and therapeutic management.

Pharmacogenetics

The use of genetic variation to identify subgroups of patients who may respond differently to certain medications represents the leading edge of personalized and precision medicine. Since its first description, the field of pharmacogenetics has expanded to study a broad range of cardiovascular drugs, and has become a mainstream research discipline (see also Chapter 9). Three principal classes of pharmacogenetic markers have emerged: (1) pharmacokinetic, (2) pharmacodynamic, and (3) underlying disease mechanism. Significant advances have identified markers in each class for a variety of therapeutics, some with the potential to improve patient outcomes (Table 7-1). Although ongoing clinical trials will determine the potential benefits of routine pharmacogenetic testing, current data support pharmacogenetic testing for certain variants on an individualized, case-by-case basis. Major pharmacogenetic variants have

been identified that are associated with commonly used cardiovascular medications (Tables 7-2 to 7-4).⁴³ Presented next is an overview of the current status for the pharmacogenetics of statins, warfarin, and clopidogrel.

Statins (see Table 7-2). Genetic testing for statin efficacy is not likely to enter clinical care, because the magnitude of association is small (approximately 10% to 15% differences in LDL cholesterol lowering), and physicians can reasonably forecast the magnitude of LDL cholesterol lowering based on statin type, dose, and baseline LDL cholesterol. By contrast, statin-induced *side effects and nonadherence* are less predictable. The solute carrier organic anion transporter family, member 1B1 gene (*SLCO1B1*, also referred to as *SLC21A6*, *OATP-C*, or *OATP1B1*) harbors a genetic variant, the *5 variant (rs4149056, Val174Ala), that interferes with the localization of this transporter to the hepatocyte plasma membrane,⁴⁴ leading to higher plasma statin concentrations.⁴⁵⁻⁴⁷ In candidate gene studies and GWASs, carriers of *5 have a fourfold to fivefold increased risk for severe, creatine kinase (CK)-positive simvastatin-induced myopathy, and a twofold to threefold increased risk for CK-negative myopathy.^{48,49}

In trials of randomly assigned statins and in observational studies, the risk for myopathy with *5 depends on the statin type: The risk is greatest for simvastatin > atorvastatin > pravastatin, rosuvastatin, or fluvastatin.^{49,50} These effects parallel the influence of the *5 allele on the clearance of these statins,^{45,47} and thus appear to be statin-specific.

Clinical guidelines do not currently recommend prospective genotyping for *SLCO1B1**5 based on the current levels of evidence, but the test is currently offered on consumer-directed genotyping platforms,

TABLE 7-1 Sources of Pharmacogenetic Variation

CATEGORY	DESCRIPTION	TYPES OF GENES	EXAMPLE DRUGS WITH: GENES
Pharmacokinetic	Variability in the concentration of drug at the site of drug effect	Drug-metabolizing enzymes Drug transporters	Warfarin: <i>CYP2C9</i> Clopidogrel: <i>CYP2C19</i> Simvastatin: <i>SLCO1B1</i> Metoprolol: <i>CYP2D6</i>
Pharmacodynamic	Variability in the drug ability to influence its target	Transmembrane receptors Intracellular enzymes	Clopidogrel: <i>P2RY12</i> Simvastatin: <i>HMGCR</i> Metoprolol: <i>ADBR1</i>
Underlying disease	Variability in the disease being treated	Often downstream or independent of drug target	HCTZ: <i>ADD1</i> Simvastatin: <i>APOE</i>

HCTZ = hydrochlorothiazide.

TABLE 7-2 Genetic Associations with the Response to Statins

GENE	VARIANT(S)	STATIN RESPONSE	STATIN TYPE
<i>APOE</i>	ε2, ε3, and ε4 haplotypes defined by alleles at rs7412 and rs429358	LDL cholesterol lowering	Class effect
<i>HMGCR</i>	H7 haplotype defined by alleles at rs17244841, rs17238540, and rs3846662	LDL cholesterol lowering	Simvastatin
<i>SLCO1B1</i>	rs4149056	Musculoskeletal side effects	Simvastatin, atorvastatin
<i>SLCO1B1</i>	rs4149056	Nonadherence	Simvastatin, atorvastatin

Modified from Voora D, Ginsburg GS: Clinical application of cardiovascular pharmacogenetics. *J Am Coll Cardiol* 60:9, 2012.

TABLE 7-3 Genetic Associations with the Response to Clopidogrel

GENE	VARIANT(S)	DRUG RESPONSE
<i>CYP2C19</i>	*2 (rs4244285)	Drug concentration, platelet function, recurrent MI, stent thrombosis
<i>CYP2C19</i>	*17 (rs3758581)	Drug concentration, platelet function, bleeding
<i>ABCB1</i>	T-T haplotype defined by T allele at C1236T (rs1128503), G2677T (rs2032582), and C3435T (rs1045642)	Drug concentration, platelet function, recurrent MI, stroke, death
<i>P2RY12</i>	F haplotype defined by following alleles: rs6798347, rs6787801, rs9859552, rs6801273, rs9848789, and rs2046934	Inhibition of platelet function

MI = myocardial infarction.

Modified from Voora D, Ginsburg GS: Clinical application of cardiovascular pharmacogenetics. *J Am Coll Cardiol* 60:9, 2012.

and is being provided to clinicians as part of the National Institutes of Health (NIH) eMERGE program.⁵¹ A potential strategy for prospective *SLCO1B1**5 testing might recommend pravastatin, rosuvastatin, or fluvastatin as first-line agents for carriers, because these drugs seem to depend the least on *SLCO1B1* for their clearance.

Clopidogrel (see Table 7-3). The *CYP2C19**2 allele is associated with a graded risk of death, MI, or stroke. Carriers of one allele (intermediate metabolizers) have an approximately 1.5-fold increased risk, and carriers of two alleles (poor metabolizers) experience a 1.8-fold increase. This pattern also extends to stent thrombosis, with an approximately 2.6-fold and 4-fold increased risk in persons with one and two *2 alleles, respectively.⁵²⁻⁵⁷ The *CYP2C19* genetic associations with platelet function correlate with the clinical response to clopidogrel in the setting of percutaneous coronary intervention (PCI). These observations formed the foundation for the U.S. Food and Drug Administration's (FDA) updating the clopidogrel label to include pharmacogenetic information. Despite having an FDA "black box warning" for efficacy in individuals carrying the *CYP2C19* genetic variant, its adoption in practice has lagged.

Warfarin (see Table 7-4). The response to warfarin has strong genetic associations with *CYP2C9*, *VKORC1*, and *CYP4F2* variants. Commercial testing and algorithms (e.g., see www.warfarindosing.org) can assist in the interpretation of genotypes. Evidence to justify and tools to enable genotype-guided warfarin therapy are thus well recognized. Until large-scale trials demonstrate a benefit for routine testing, physicians may choose to pursue testing in selected patients in whom it may be beneficial, for (1) diagnosing those with

complications from warfarin therapy (e.g., hemorrhage); (2) predicting dose for those at high risk of bleeding (e.g., "triple therapy" with aspirin, clopidogrel, and warfarin); or (3) weighing the costs of newer anticoagulants against warfarin.

For cardiovascular pharmacogenomics, the pace of genetic discovery has outstripped the generation of evidence justifying its clinical adoption for many of the findings to date. Until the evidentiary gaps are filled, however, clinicians may choose to target therapeutics to individual patients whose genetic backgrounds indicate that they stand to benefit the most from pharmacogenetic testing.

TABLE 7-4 Genetic Associations with the Response to Warfarin

GENE	VARIANT(S)	DRUG RESPONSE
<i>CYP2C9</i>	*2 (rs1799853) *3 (rs1057910)	Drug concentration, warfarin dose requirements, out-of-range INR values, hemorrhage
<i>VKORC1</i>	−1639 (rs9923231)	Warfarin dose requirements, out-of-range INR values
<i>CYP4F2</i>	rs2108622	Warfarin dose requirements

INR = international normalized ratio.

BARRIERS AND SOLUTIONS TO THE INTEGRATION OF GENOMICS INTO CARDIOVASCULAR MEDICINE

The implementation and adoption of personalized and precision cardiovascular medicine in practice will require several key strategies.⁵⁸ One such strategy is the development of enabling infrastructure at the level of specialized laboratory resources (i.e., coordinated biobanking linked to clinical data; informatics support and standards; easy access to genome-wide technologies and core laboratories). In addition, considerable bioinformatics and information technology development is required to make use of the deluge of data that is emerging from these resources: informatics and statistical specialists who can analyze complex multidimensional data; reliable, interoperable electronic health records linked to molecular data; integration of research, clinical, and molecular data; and clinical decision support. Moreover, there is a critical shortage of physicians trained in quantitative skills and decision analysis (understanding of human behaviors and decision making; elucidation of the biologic, psychological, and social factors in decision making). Further integration of personalized medicine into the clinical workflow requires overcoming several key barriers,⁵⁹ including the development of evidence to support personalized and precision medicine technology use in clinical care, provider understanding and acceptance of these technologies, implementation and integration into clinical workflows, standards for regulation and reimbursement, and education of patients and providers on the benefits and risks of genomic testing (Table 7-5).

FUTURE PERSPECTIVE: TOWARD PERSONALIZED AND PRECISION CARDIOVASCULAR MEDICINE

Cardiovascular medicine is poised to become more personalized and precise through the translation of genome-based discoveries to clinical practice. Several parallel approaches should speed the elucidation of the genomic basis of many cardiovascular diseases. Rare susceptibility variants will rapidly be identified through exome and whole-genome sequencing programs. Detailed cataloging of tissue-specific expression profiles—including the transcriptome, proteome, and metabolome—will yield important insight on the intrinsic biology of disease, along with the environmental and lifestyle impacts on disease. “Framingham 2.0” represents a model that incorporates genomics fully into longitudinal population studies with detailed environmental and geospatial data. The complete integration of genomics and electronic health records is another critical innovation required for a truly systems medicine approach that delivers genetic and genomic biomarkers for potential clinical use. The clinician, fully armed with the knowledge, informatics, and clinical decision support to interpret and use complex data, will be an essential facilitator of personalized and precision cardiovascular medicine and the improvement of cardiovascular public health.

As physicians, we seek to understand the root cause of human disease. Human genetics provides a unique tool for generating new hypotheses about the root causes of disease based on genome-wide searches in the human population that are unlimited by prior assumptions about the underlying pathophysiologic processes. Over the past several decades, application of the principles discussed here has successfully identified the causative genes for a range of cardiovascular diseases. This information has provided explanations to our patients, improved the ability to predict risk for disease, and most importantly, enabled understanding of the pathophysiology as a foundation for designing rational approaches to improving prevention and therapy.¹ This chapter reviews the principles of human genetics used to make gene discoveries and to translate these findings to improve patient care. We highlight these principles in the context of a clinical case presentation.

INHERITED BASIS FOR THE VARIATION IN RISK FOR CARDIOVASCULAR DISEASE

PATIENT CASE, PART I. A 44-year-old man (JS) is seen in a cardiologist's office for a follow-up visit after having suffered an ST-segment elevation myocardial infarction (STEMI) and undergone treatment consisting of primary angioplasty and placement of a drug-eluting stent. His cardiovascular risk factors before STEMI included a fasting low-density lipoprotein cholesterol (LDL-C) level of 235 mg/dL and active cigarette smoking. His body mass index (BMI) is 25 kg/m², he does not have a history of type 2 diabetes, and he is normotensive. His father died at 45 years of age as a result of myocardial infarction (MI), and his paternal uncle suffered an MI at 49 years of age. He has two brothers, 43 and 39 years old; both are free of clinical cardiovascular disease. The 43-year-old brother (KS) has an elevated LDL-C level (214 mg/dL). The 39-year-old brother (LS) has an LDL-C level of 130 mg/dL and a high-density lipoprotein cholesterol (HDL-C) level of 29 mg/dL. The pedigree of the family is shown in **Figure 8-1**.

Many cardiovascular diseases cluster within families, and studies of familial aggregation can determine the extent to which inherited DNA sequence variants contribute to these patterns. A family history of premature coronary heart disease (CHD) elevates the risk for CHD in offspring approximately threefold.² Family history is an important risk factor for almost every cardiovascular disease—including atrial fibrillation, congenital heart disease, and hypertension—but familial clustering of disease can reflect shared environment in addition to shared genetic sequence.

Heritability—the fraction of interindividual variability in risk for disease attributable to additive genetic influences—is a commonly used measure for isolating the role of shared genetic sequence. The remaining variability among individuals results from all other contributors: environmental influences on disease, nonadditive (*epistatic*) genetic effects (e.g., gene-gene interactions or gene-environment interactions), error in the measurement of relatedness or disease, and random chance. For most clinically important traits (diseases and risk factors), empiric estimates of heritability range from 20% to 80% (see Online Mendelian Inheritance in Man, available at www.ncbi.nlm.nih.gov:80/entrez/query.fcgi?db=OMIM, for comprehensive information).

A BRIEF PRIMER ON MOLECULAR BIOLOGY

Genes are encoded in DNA, a polymeric molecule with two strands in a configuration known as a double helix. The “code” comprises four different DNA bases—adenine (A), cytosine (C), guanine (G), and thymine (T)—linked together in nonrandom order. The two strands contain redundant information by virtue of complementarity—an adenine on one strand is always paired with a thymine on the other strand, and a cytosine on one strand is always paired with a guanine on the other strand. Thus double-strand DNA can be considered to be a sequence of A-T, T-A, C-G, and G-C base pairs (**Fig. 8-2**).

Human DNA is organized into a total of 23 pairs of chromosomes, with each chromosome spanning millions of base pairs. The 46 chromosomes in total make up the genome. Each chromosome has numerous genes, which contain so-called coding DNA, separated by large stretches of noncoding DNA. A process called transcription copies the information in the DNA sequence into single-strand RNA, a polymer that is structurally similar to DNA but uses uracil (U) in place of thymine (T). Subsequently, the process of translation converts the RNA sequence into an amino acid sequence that makes up a protein, which can serve in a variety of roles (structural elements, enzymes, hormones, etc.). Thus genetic information flows from DNA to RNA to protein in what is classically known as the “central dogma” of molecular biology (**Fig. 8-3**).

One of the consequences of the central dogma is that a change in the DNA sequence in the genome, if it should occur in or near a gene, can result in a change in the protein encoded by the gene, which in turn can have important consequences on the phenotype of an organism. Phenotype refers to any observable characteristic in a human being. Changes in DNA sequence leading to phenotypic

changes underlie most of the heritability of diseases that have a genetic component.

Epigenetics pertains to phenotypic changes caused by DNA-level modifications that do not involve the DNA sequence, typically structural modifications either of certain DNA bases or of the proteins

(called histones) in which the DNA is packaged. These changes can result in altered levels of RNA being transcribed from the DNA, which in turn results in altered levels of protein. In some cases the epigenetic changes are transmitted from parents to offspring, and thus can represent an additional source of phenotypic heritability.

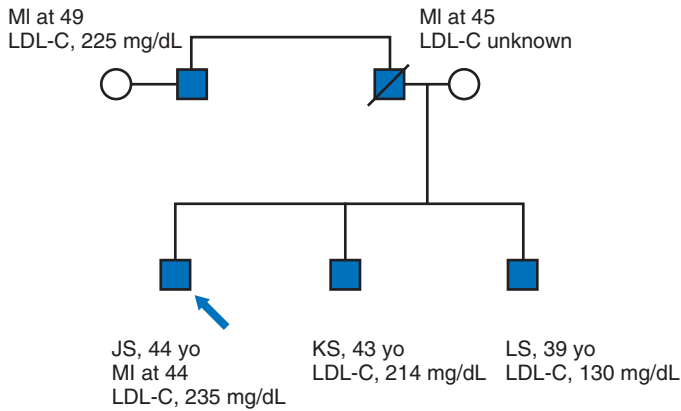

FIGURE 8-1 Pedigree of the case patient JS (indicated by the arrow), who had a STEMI when he was 44 years old (yo).

MODES OF INHERITANCE

The genetic architecture of a disease refers to the number and magnitude of genetic risk factors that exist in each patient and in the population, as well as their frequencies and interactions. Diseases can be due to a single gene (monogenic) in each family or to multiple genes (polygenic). Identifying genetic risk factors is easiest when only a single gene is involved and this gene has a large impact on disease in that family. In cases in which a single gene is necessary and sufficient to cause disease, the condition is termed a mendelian disorder because the disease tracks perfectly with a mutation (in the family) that obeys Mendel's simple laws of inheritance.

For monogenic disorders, modes of inheritance include autosomal dominant, autosomal recessive, and X-linked. In autosomal dominant disorders, a single defective copy of a gene (either the maternal or paternal copy for every autosomal gene) suffices to cause the phenotype. In autosomal recessive disorders, both copies need to be

FIGURE 8-2 Schematic representation of the DNA double helix. The specificity of genetic information is carried in the four bases—guanine (G), adenine (A), thymine (T), and cytosine (C)—that extend inward from a sugar phosphate backbone and form pairs with complementary bases on the opposing strand.

FIGURE 8-3 Flow of genetic information. Transcription in the nucleus creates a complementary RNA copy from one of the DNA strands in the double helix. mRNA is transported into the cytoplasm, where it is translated into protein.

defective to lead to the phenotype. In X-linked disorders, the defective gene resides on the X chromosome. Given that men have only one X chromosome and women have two X chromosomes, men who carry the defective copy are affected with the disorder, whereas women are unaffected carriers.

Most common cardiovascular diseases, however, do not obey Mendel's simple laws of inheritance but rather are complex—the result of an interplay between multiple genes and the environment. For these polygenic disorders, variants in more than one gene are needed to cause a disease. Accordingly, in these cases it becomes difficult to understand a disease by studying a single family. A corollary is that each contributing gene variant may have a small phenotypic effect that is not obvious by comparing a few people with and without that variant. For these reasons, elucidating the genetic architecture of a complex disorder is more feasible by studying a large population.

The patient case presented earlier describes both discrete cardiovascular phenotypes (i.e., traits defined by their presence or absence based on a set of criteria) and quantitative phenotypes. MI is a discrete (also called dichotomous) phenotype, whereas blood pressure, LDL-C, HDL-C, and BMI are continuous cardiovascular traits. In the general population, most of these traits display a complex pattern of inheritance.

For many complex traits, however, some subtypes of the disease are monogenic in inheritance. In our patient case, the co-occurrence of high LDL-C, early-onset MI, and a family history of premature MI suggests a specific mendelian disorder, namely, familial hypercholesterolemia (FH).³ In FH, the extremely high LDL-C level and MI result from defects in the LDL receptor gene. Severely high LDL-C and early MI can also be caused by defects in other genes, including proprotein convertase subtilisin/kexin type 9 (*PCSK9*) and apolipoprotein B (*APOB*). Other examples of monogenic subtypes of complex traits include extremely high or low blood pressure caused by rare mutations in genes involved in renal salt handling; extremely low LDL-C as a result of mutations in *APOB*, *PCSK9*, or *ANGPTL3*; and extreme obesity caused by mutations in *MC4R*.

APPROACHES TO DISCOVERING THE INHERITED BASIS FOR CARDIOVASCULAR DISEASE

Human Genetic Variation

The human genome contains about 6 billion base pairs across the 46 chromosomes. Approximately 1% of the genomic DNA is coding DNA, which comprises an estimated 20,000 genes.⁴ Although most of the DNA in the genome is shared among all human beings, variations in the DNA sequence—occurring in both coding DNA and noncoding DNA—distinguish individuals from one another. These DNA sequence variants partly account for why a disease is more or less likely to develop in some individuals or why some respond more favorably or more adversely to a medication (see also Chapters 7 and 9).

As alluded to earlier, some DNA sequence variants have large phenotypic effects—meaning that they can cause disease single-handedly. These DNA sequence variants tend to be rare (and sometimes unique to a single person or family) because natural selection weeds them out of a population. Classically, they cause monogenic disorders. Other DNA sequence variants commonly occur in a population and tend to have smaller phenotypic effects. Typically it is these variants, in combination, that cause polygenic disorders. Because of natural selection, in general there is an inverse relationship between the frequency of a DNA sequence variant and the phenotypic effect conferred by that variant. For example, such a relationship is observed for gene variants that affect LDL-C in the population (Fig. 8-4).⁵⁻⁸

Coding sequence variants potentially disrupt the function of genes and their protein products (Fig. 8-5).⁹ Some coding variants do not affect the amino acid sequence of a protein; these are known as synonymous variants and do not usually have any phenotypic consequences. Other coding variants can cause a variety of alterations in a protein—substitution of a single amino acid in a protein with a

different amino acid (missense), premature truncation of a protein (nonsense), scrambling of the amino acid sequence past the site of the variant (frameshift), or insertion or deletion of amino acids. Any of these so-called nonsynonymous variants can have phenotypic effects ranging from negligible to profound, although nonsense and frameshift variants tend to be more deleterious than missense variants to protein function. Finally, sequence variants at splice sites (the first and second bases after the end of each exon and before the beginning of each exon) can lead to a severely disrupted protein product missing an entire exon.

Noncoding variants, although they do not directly affect the amino acid sequences of proteins, can cause phenotypic changes in other ways. For example, a noncoding variant near a gene might affect transcription of the gene and result in an increased amount of RNA being produced from a gene, and consequently an increased amount of the protein product.¹⁰ Noncoding variants can affect the processing of RNA in several other ways.

In addition to genes, the genome harbors a number of expressed RNA molecules that do not code for protein; such RNA includes microRNA and large intergenic noncoding RNA (lincRNA). Both these categories of noncoding RNA have been demonstrated to interact with and modulate the activity of coding RNA, thereby regulating protein levels. For example, a given microRNA might physically bind to complementary sequences in a large number of coding RNA molecules and result in either suppression of RNA translation into proteins or degradation of the RNA. A noncoding variant that falls in the midst of a microRNA might impair (or enhance) its ability to interact with specific coding RNA and result in phenotypic changes.

DNA sequence variants, also known as polymorphisms (derived from Greek words meaning “multiple forms”), consist of three major classes. Single-nucleotide polymorphisms (SNPs) involve the alteration of a single DNA base pair in the genome. They are the most common and best cataloged of the DNA variants, with tens of millions having been identified to date across all human populations. Variable number tandem repeats (VNTRs) involve a variable number of repeats of a short DNA sequence at a genomic location; the number of repeats ranges from very few to thousands. Copy number variants (CNVs) involve a variable number of repeats of a long DNA sequence (more than 1000 base pairs), typically ranging from zero to one or a few repeats. An indel (an abbreviation of insertion/deletion) is a type of DNA variant in which a sequence is either present (insertion) or absent (deletion); it could be either a special type of a VNTR or a special type of a CNV, depending on the size of the involved sequence.

Characterizing Human Genetic Variation: Genotyping and Sequencing

In most cases a person has two copies of each DNA sequence because of the presence of paired chromosomes (the exceptions are DNA sequences on the X or Y chromosome in men, because these two chromosomes are entirely different). The two copies are known as alleles. For a DNA variant, the genotype is the identity of the two alleles at the site of the variant. The two alleles may be identical, in which case the person is said to be homozygous for the allele. If the two alleles are different, the person is heterozygous at the DNA variant. A haplotype is a series of genotypes at nearby sites of DNA variants. Because the haplotype is located on a single region of the chromosome, it tends to remain linked together as it passes from parents to offspring.

For polymorphisms that are primarily present in just two forms (typical of SNPs, i.e., one DNA base versus another DNA base, but not for VNTRs, which are usually found in at least a few forms, i.e., different numbers of repeats), the allele found more commonly in a given population is termed the major allele, with the less common allele being the minor allele. Common variants are so defined by virtue of the frequency of the minor allele being greater than 5% in the population. Low-frequency variants have a minor allele frequency of between 0.5% and 5%; rare variants have less than a 0.5% frequency. Rare variants are typically referred to as mutations. In some

cases, mutations are so rare that they are found only in one individual or in one family.

Two types of methods can be used to determine genotypes at the sites of DNA variants. In the first type, a genotyping technology directly ascertains the genotype at a single location in the genome. In the second type, polymerase chain reaction (PCR) is used to amplify the region of DNA immediately surrounding the site of the DNA variant (**Fig. 8-6**). The PCR product is subjected to DNA sequencing, which indirectly determines the genotype. The first type is generally cheaper—indeed, fabricated “chips” can directly genotype millions of DNA variants at a time—but requires optimization beforehand. Thus direct genotyping is most useful for common and low-frequency variants that have already been cataloged. The second type is more expensive and can be used only at one location at a time, but it can be flexibly adapted to any location in the genome. This approach can be used to discover previously uncataloged rare DNA sequence variants.

In recent years, a third type of method has been devised to characterize a person's genetic variation. This method entails the use of any of a group of techniques known as next-generation DNA sequencing.¹¹ Although the operational details differ, these techniques share the ability to sequence billions of DNA base pairs at a time within a reasonable time frame and at a reasonable cost. The techniques have been applied successfully to efficiently sequence the entirety of a patient's coding DNA, known as the exome, which accounts for about 1% of the genome.^{12,13} More recently, sequencing the entirety of a patient's genome for a few thousand U.S. dollars within 24 hours has become feasible, with the highly publicized “thousand-dollar genome” expected to emerge very soon.

Although performing DNA sequencing remains more expensive than direct genotyping, the decreasing cost of whole-genome sequencing will soon enable it to be performed in large cohorts of people. The advantage of whole-genome sequencing is that it determines genotypes at the locations of all known DNA sequence variants in a single experiment and, at the same time, identifies previously unknown DNA variants that are unique to the individual.

Study Designs to Correlate Genotype with Phenotype

Approaches to correlate genotype with phenotype are highlighted in **Figure 8-7**. The x axis shows the frequency of the allele in the population, from rare to common; the y axis shows the size of the phenotypic effect conferred by the DNA sequence variant allele, from small to large. As described earlier, because of evolution and natural selection, an inverse relationship exists between allele frequency and effect size. Typically, to detect common DNA sequence variants of small to modest effect (e.g., increase in risk of 5% to 50%), genotyping characterizes the DNA sequence variation, and population-based association links genotype with phenotype. Rare variants with larger effect are discovered by sequencing to characterize their DNA sequence variation. One of two major approaches—family-based studies or extreme-phenotype studies—can be used to correlate rare variants with phenotype. Variants of low frequency (0.5% to 5%) can be approached by either genotyping or sequencing, and any of the three study designs may be useful in linking genotype with phenotype.

Family-Based Studies

PATIENT CASE, PART II. The cardiologist refers the 45-year-old patient (JS) who recently suffered an MI to a geneticist for evaluation. The geneticist suspects that the patient has FH and arranges for clinical sequencing of the *LDLR*, *APOB*, and *PCSK9* genes. These tests identify a mutation in the *PCSK9* gene: a T → A substitution in exon 2 at nucleotide 625, which predicts a substitution of arginine at codon 127 for the conserved serine (S127R). This mutation has been proved to lead to gain of PCSK9 function and cause autosomal dominant hypercholesterolemia.¹⁴

Two major study designs have been used to identify the gene mutations responsible for monogenic disorders. Both take advantage of

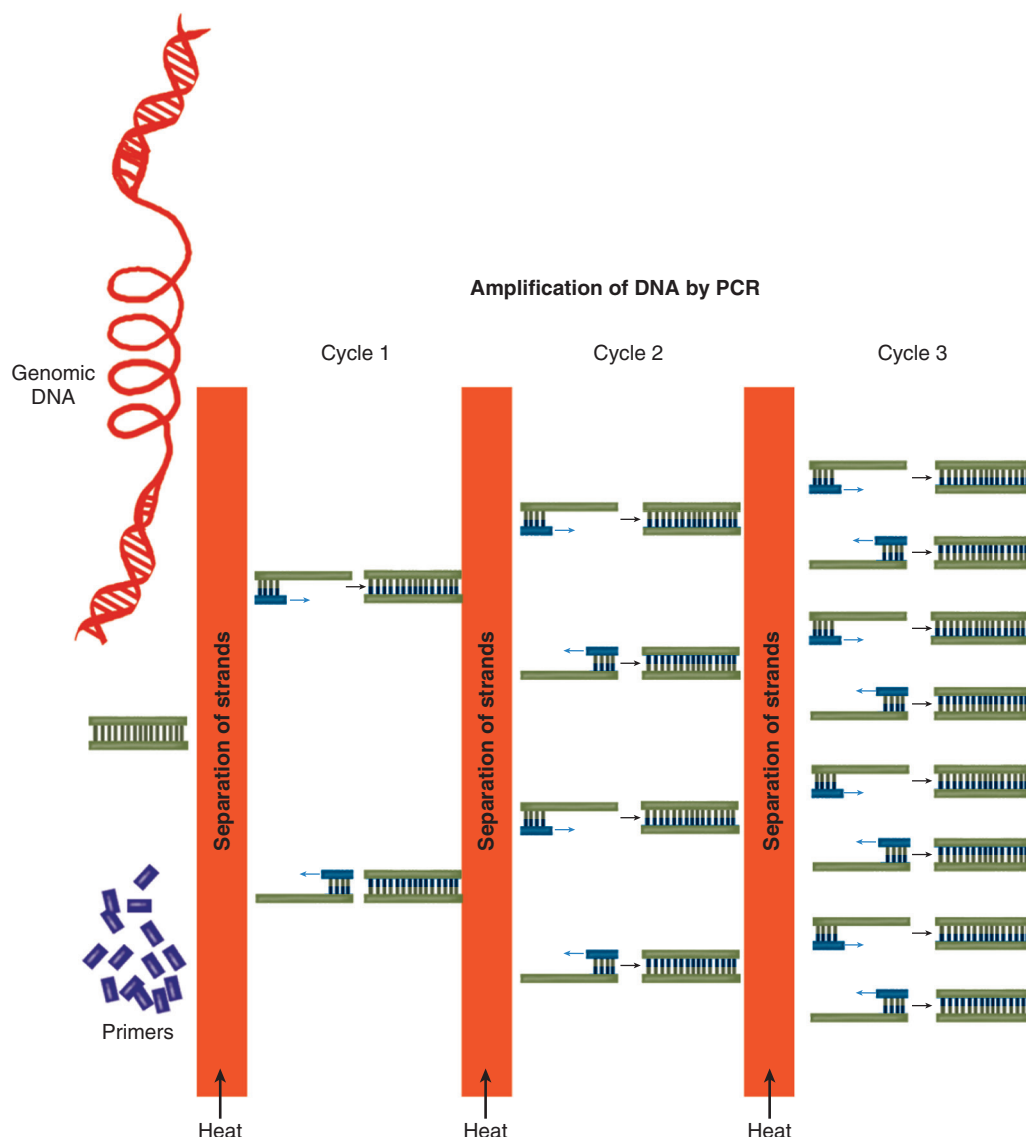

FIGURE 8-6 DNA amplification with PCR. Synthetic primers corresponding to the 5' and 3' ends of the DNA sequence are chemically synthesized. The double-stranded DNA is melted by heating to 92°C, followed by cooling to 72°C to anneal the primers. A heat-stable DNA polymerase amplifies each strand of the target sequence, which produces two copies of the DNA sequence. The process is repeated multiple times to achieve amplification of the target sequence.

family relationships. Classic linkage studies entail the genotyping of several hundred or thousand DNA variants (usually VNTRs with repeats that are two to six base pairs in length, also known as microsatellite markers) distributed across the genome. Linkage analysis identifies any markers that are strongly “linked” to the disease. For dominantly inherited disorders, linkage can be observed when one particular allele of the marker is found only in family members with the disease (“affecteds”) and not in healthy family members (“unaffecteds”); for recessively inherited disorders, linkage is observed when two copies of a particular allele are found only in family members with the disease and not in healthy family members. The degree of linkage for each genomic marker with affected status is calculated to yield a metric known as the logarithm of odds (LOD) score. A LOD score higher than 3.0 is considered significant evidence of linkage.

As a practical matter, a high LOD score for a particular marker suggests that the causal disease mutation lies within several megabases (i.e., millions of base pairs) of the marker. This region of interest typically harbors dozens, if not hundreds, of candidate genes. The region can sometimes be narrowed further by genotyping a set of markers clustered around the original marker and assessing for linkage, a process called positional cloning. Identification of the

disease mutation entails sequencing candidate genes in the hope of finding a rare coding variant. Traditionally, sequencing of a large number of genes was prohibitively expensive, and one would have to judiciously pick a limited number of candidate genes thought most likely to have the causal mutation—and often come up empty-handed.

The second study design has been made possible by advances in next-generation DNA sequencing technologies. Rather than sequencing a few candidate genes, one can now perform exome sequencing and capture the coding DNA of all approximately 20,000 human genes in a single, relatively affordable experiment. In this study design, one chooses a few affected family members, performs exome sequencing on their DNA samples, and filters through the sequencing data to identify the handful of rare variants that are shared by all affecteds.¹⁵ This list of variants can be narrowed down further in several ways, such as confirming that a variant is not present in unaffecteds or simultaneously performing a linkage study and filtering for variants that are close to a marker with a high LOD score.

Once the rare gene variant thought most likely to be the causal mutation is selected, it can be confirmed by sequencing the gene in unrelated individuals who have the same disorder. If some of these individuals have mutations in the same gene (either the same rare

variant or, more likely, different variants), it strongly argues that the gene is responsible for the disease.

Extreme-Phenotype Studies

Another approach to gene discovery is to identify individuals in a population who are at the extremes of a phenotype.¹⁶ For a quantitative phenotype such as blood cholesterol level, this might entail finding a sizable number of people with extremely high cholesterol and people with extremely low cholesterol. For a discrete phenotype such as MI, the desired individuals might be young people with premature disease versus elderly people with multiple risk factors but no evidence of coronary artery disease (CAD).

DNA samples from these extreme cohorts undergo either candidate gene sequencing, exome sequencing, or even whole-genome sequencing. The analysis entails identifying genes that have a preponderance of rare variants in one group versus the other group. For example, if a particular gene were to display a significantly higher frequency of rare variants in young people with MI than in elderly people without CAD, it would argue for that gene being causal for MI. Conversely, if the gene had a higher frequency of rare variants in elderly people without CAD than in young people with MI, the gene might protect against disease.

Population-Based Studies

Family-based studies are poorly suited to study polygenic disorders in which each contributing DNA variant has a small or moderate effect. Because these DNA variants tend to be common in a given population, population-based studies are better designed to detect their small effects with statistical rigor.

The genome-wide association study (GWAS) is the primary population-based study design.^{17,18} In a GWAS, DNA samples from many unrelated individuals in a population—as many as hundreds of thousands of people—undergo genotyping of millions of SNP markers across the genome using chips. The analysis entails a search for SNPs that have robust statistical associations with the phenotype of interest. For a GWAS on a quantitative phenotype such as blood cholesterol level, each SNP is evaluated to determine whether individuals with one genotype at that SNP have on average a significant difference in cholesterol level from individuals with another genotype.

For a GWAS on a discrete phenotype such as MI, the study compares a group of individuals with the phenotype and a group of individuals without the phenotype (cases versus controls). Each individual SNP is evaluated to determine whether its minor allele frequency differs between the cases and controls (Fig. 8-8).

With any GWAS, because so many SNPs are being evaluated independently, the traditional statistical significance threshold of $P < 0.05$ is not valid and must be adjusted for the number of SNPs tested. The number of independent common SNPs tested in a single experiment is approximately 1,000,000. Accordingly, it is common practice with a GWAS to use a statistical significance threshold of $P < 5 \times 10^{-8}$ (i.e., Bonferroni correction of the traditional P value of 0.05 for 1,000,000 independent tests). The need to meet a very rigorous significance threshold, as well as the fact that most DNA variants contributing to a polygenic trait have small effects, often dictates studying very large numbers of people to carry out a GWAS successfully.

GWAS results are typically displayed in a “Manhattan plot,” with the x axis representing each variant in chromosomal order and the y axis plotting $-\log_{10}$ of the P value associating each variant with the

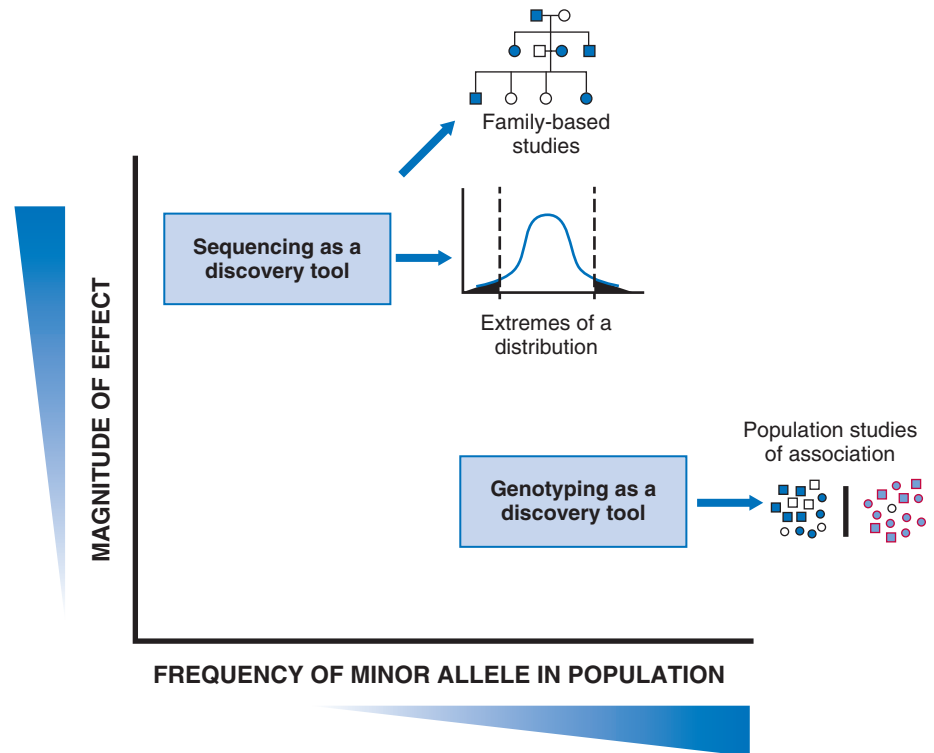

FIGURE 8-7 Approaches to correlate genotype with phenotype.

FIGURE 8-8 Analysis scheme for a GWAS involving a dichotomous phenotype. Step 1. Compare frequency of genetic variant in cases and controls. Carriers of a variant allele are shown in pink, and noncarriers are shown in blue. Boxes represent men and circles represent women. Here the variant allele is more frequent in cases compared with controls. Step 2. For each genetic variant (typically 300,000 to 1,000,000 in each experiment), generate P value for the difference in frequency being a chance observation.

trait of interest. SNPs exceeding a P value threshold of $P < 5 \times 10^{-8}$ are considered “genome-wide significant” and are the least likely to be false-positive results. The Manhattan plot from a large-scale GWAS for CAD is displayed in Figure 8-9. A total of 25 chromosomal loci exceeded genome-wide significance in this study.

A GWAS uses a far more dense distribution of markers across the genome and data from far more people than a linkage study does. Furthermore, a GWAS takes advantage of the genome’s discrete recombination hot spots, between which regions of DNA remain relatively intact as they are passed from parents to offspring. Consequently, the resolution of a GWAS is much higher than that of a linkage study; rather than megabases, the locus of interest is defined by flanking recombination hot spots, which on average occur just tens to hundreds of kilobases apart. For a given SNP with a positive association with a phenotype, this considerably narrows the number of candidate causal genes. Also in contrast to linkage studies, GWAS

FIGURE 8-9 Graphic summary (Manhattan plot) of genome-wide association results. The x axis represents the genome in physical order; the y axis shows $-\log_{10} P$ for all SNPs. Data from the discovery phase are shown in circles, and data from the combined discovery and replication phases are shown in stars. Genes at the significant loci are listed above the signals. Known loci (before publication of this work) are shown in red, and newly discovered loci from this work are shown in blue. (From Schunkert H, König IR, Kathiresan S, et al: Large-scale association analysis identifies 13 new susceptibility loci for coronary artery disease. *Nat Genet* 43:333, 2011.)

have successfully pinpointed noncoding causal DNA variants that affect gene expression.

ILLUSTRATIVE EXAMPLES

In presenting examples of the various approaches described above, we focus on LDL-C—whether in the context of monogenic lipid disorders such as FH or in the context of the blood LDL-C level as a polygenic, quantitative trait.

Mendelian Disease Using Classic Linkage

FH is a monogenic disorder in which patients have extremely high blood LDL-C levels that result in abnormal deposition of cholesterol (xanthomas) and a severely increased risk for premature MI, as early as childhood. Initial studies in the 1970s and 1980s by Brown, Goldstein, and colleagues demonstrated that most cases of FH result from mutations in the LDL receptor gene (*LDLR*).¹⁹ In 1989, a subset of cases were found to result from mutations in the apolipoprotein B gene (*APOB*).²⁰ Following these discoveries, other cases remained in which neither *LDLR* nor *APOB* mutations appeared to be responsible.

Boileau and coworkers identified French families affected by FH without apparent *LDLR* or *APOB* mutations and, in performing a linkage study, identified a region on chromosome 1 where markers had strong linkage to the disease.¹⁴ Using positional cloning, they narrowed the region to an interval containing 41 genes. One gene, *PCSK9*, was a strong candidate because a similar gene had previously been reported to be involved in cholesterol metabolism.

In sequencing *PCSK9*, they found two different rare variants in different families. Subsequent studies in mice confirmed that *PCSK9* is a bona fide regulator of blood cholesterol levels, and indicated that the mutations discovered were likely to be gain-of-function rather than loss-of-function mutations.²¹

Mendelian Disease Using Direct DNA Sequencing

Schonfeld and colleagues identified a family in which four siblings displayed extremely low blood LDL-C, HDL-C, and triglyceride levels—an apparently recessive disorder termed familial combined hypolipidemia.²² A linkage study could not identify the causal gene because of the prohibitively large number of genes in the linkage region. Years later, following the advent of exome sequencing, DNA samples from two of the siblings were subjected to the technique. In a comparison of the siblings' exomes, only one gene harbored rare DNA variants in both alleles in both siblings—the angiopoietin-like 3 (*ANGPTL3*) gene, which had been implicated previously in the metabolism of triglycerides but not LDL-C. Of note, the siblings had two different mutations, each of which was a nonsense mutation, consistent with total loss of *ANGPTL3* function. Subsequent studies confirmed the presence of various *ANGPTL3* mutations in unrelated individuals with familial combined hypolipidemia.

Complex Trait Using Extremes in a Population

Shortly after the discovery of *PCSK9* as a causal gene in FH, Hobbs, Cohen, and colleagues hypothesized that loss-of-function variants in

FIGURE 8-10 Distribution of LDL-C (**A**) and risk for CHD (**B**) in carriers versus noncarriers of nonsense mutations in the *PCSK9* gene. (From Cohen JC, Boerwinkle E, Mosley TH Jr, Hobbs HH: Sequence variations in *PCSK9*, low LDL, and protection against coronary heart disease. *N Engl J Med* 354:1264, 2006.)

PCSK9 may contribute to differences in blood cholesterol levels in the general population. Reasoning that individuals with low LDL-C levels were more likely to have such loss-of-function variants (because gain-of-function mutations cause increased LDL-C levels in FH), they sequenced *PCSK9* in individuals at the phenotypic extreme in the multiethnic Dallas Heart Study—those with the lowest LDL-C levels.^{23,24} Several of these individuals had one copy of either of two different nonsense variants in the gene. The investigators then specifically genotyped at the sites of the two nonsense variants in the entire Atherosclerosis Risk in Communities study and found that together, 2.6% of the black subjects in the study had either of the two variants. These individuals had on average a 28% reduction in LDL-C when compared with those without *PCSK9* variants. Subsequent work demonstrated that individuals with *PCSK9* nonsense variants experience a significant reduction in the risk for incident CHD (Fig. 8-10). Notably, individuals with loss-of-function variants in *PCSK9* appear to suffer no adverse clinical consequences, thus suggesting that therapies directed against *PCSK9* would offer beneficial cardiovascular effects without any accompanying undesirable effects.

Complex Trait Using Genome-Wide Association

Starting in 2007, GWASs were performed on collections of individuals of European descent to identify SNPs associated with blood LDL-C, HDL-C, triglycerides, and/or total cholesterol levels. Each year brought a successively larger study and culminated in a collaborative study involving approximately 100,000 people in 2010.⁵ This study identified a total of 95 loci associated with one or more of the lipid phenotypes. Remarkably, a third of the loci have genes previously known to be involved in lipid metabolism; indeed, more than a dozen genes had formerly been found to harbor rare DNA variants responsible for monogenic lipid disorders, including *LDLR*, *APOB*, *PCSK9*, and *ANGPTL3*. The other two thirds of the loci presumptively harbor novel lipid-regulating genes, and considerable effort is now focused on characterizing the functions of some of these genes. Some examples include *GALNT2*, *SORT1*, and *TRIB1*.

CLINICAL APPLICATION OF GENETIC FINDINGS

Risk Prediction

PATIENT CASE, PART III. The two brothers of the patient JS are referred to a cardiologist for assessment of risk for MI. Both brothers are asymptomatic but are worried about their strong family history and that JS suffered a coronary event at a similarly young age. They inquire whether they have an increased risk for a coronary event, whether that risk can be quantified, and whether they should be changing their lifestyle or taking any medications. Both patients undergo DNA sequencing to determine whether they carry the *PCSK9* mutation responsible for disease in JS. The 43-year-old brother (KS) carries *PCSK9* S127R, but the 39-year-old brother (LS) does not.

Identifying individuals at increased risk for cardiovascular disease and implementing preventive interventions to reduce that risk are key goals of biomedicine (see Chapters 7 and 42). Genetic markers have long been considered a promising tool to discern patients at increased risk. The use of genetic markers to assess risk entails consideration of two scenarios.

The first is risk prediction in the context of a family that suffers from a mendelian disorder. Here, a single defective gene is responsible for disease in the family. The central question is whether the asymptomatic family member carries the causal mutation (or two mutations for a recessive disease). Direct DNA sequencing can determine mutation status and whether the mutation is present, which typically means a near-certain risk for disease. However, complexities may exist in even a single-gene disorder.¹ Among carriers of a mendelian mutation in a given family, some may exhibit the condition and others may not. Penetrance refers to the proportion of individuals with a given genotype who exhibit the phenotype associated with the genotype. In many mendelian cardiovascular conditions inherited in an autosomal dominant manner, evidence exists for incomplete penetrance. For example, Hobbs and colleagues reported that in a pedigree with FH caused by a point mutation in *LDLR*, only 12 of 18 heterozygotes had high LDL-C (>95th percentile), whereas some of the remaining 6 heterozygotes had LDL-C as low as the 28th percentile for the

population.²⁵ The lack of a high-cholesterol phenotype given the same genotype may be due to modifier genes or environmental influences.

The second scenario uses genetics to predict risk for a common, complex disease. Here, disease results from the interplay of multiple genetic and nongenetic factors. The central questions are whether genetic markers can identify a subset of the population at higher risk for disease and whether effective interventions can be allocated to this subset of individuals to reduce their risk. For example, we commonly use a nongenetic marker, the presence of type 2 diabetes mellitus, to identify a subset of the population at higher risk for CHD (those with type 2 diabetes have a twofold increase in CHD).²⁶ We target statin intervention to this group to reduce their absolute risk for CHD.

Use of the GWAS approach has recently identified 45 common variants for CAD or MI, thereby permitting construction of a genetic risk score using mapped variants.²⁷ For the first 12 common variants mapped for CAD or MI using GWAS, a simple genetic risk score ranging from 0 to 24 alleles was generated (i.e., each individual can carry 0, 1, or 2 copies of the risk allele at each of these 12 sites), with 0 being ideal and 24 being the most unfavorable.²⁸ The distribution of this genetic risk score in the population approaches normal. Those in the top quintile of this distribution (the 20% of the population with the highest scores) had an approximately 1.7-fold increased risk for incident CHD, even after accounting for all other cardiovascular risk factors.

Will this information have clinical usefulness? Debated at present is whether young and middle-aged individuals (i.e., men 30 to 50 years of age and women 40 to 60 years of age) should be treated with a statin to prevent a first MI. Based on the genetic results presented earlier, one approach could be to use a genetic risk score to identify the subset of individuals at highest genetic risk and target statin treatment to these individuals. This hypothesis remains to be tested formally in randomized controlled trials.

Distinguishing Causal from Reactive Biomarkers

PATIENT CASE, PART IV. The 39-year-old brother of the patient JS has an HDL-C level of 29 mg/dL. Does his low HDL-C concentration causally contribute to risk for MI?

Hypotheses concerning causative agents for complex diseases have often initially come from observational epidemiology. In a 1961 paper titled “Factors of Risk in the Development of Coronary Heart Disease,” William Kannel and colleagues in the Framingham Heart Study established an association of total plasma cholesterol with future risk for CHD.²⁹ Since then, hundreds of soluble biomarkers have similarly been associated with risk for CAD (see also Chapter 10). How many of these biomarkers directly cause CAD, how many simply reflect other causal processes, and why is this question important? Both causal and noncausal biomarkers may be helpful in predicting risk for future disease, but only a causal biomarker may be appropriate as a target of therapy. The ultimate proof of causality in humans is a randomized controlled trial testing whether a treatment that alters the biomarker will affect risk for disease. But, because clinical trials are expensive and time-consuming, having evidence in humans before engaging in a clinical trial would be helpful.

In a technique termed mendelian randomization, DNA sequence variants are used to address the question of whether an epidemiologic association between a risk factor and disease reflects a causal influence of the former on the latter.³⁰⁻³² In principle, if a DNA sequence variant is known to directly affect an intermediate phenotype (e.g., a variant in the promoter of a gene encoding a biomarker that alters its expression) and the intermediate phenotype truly contributes to the disease, the DNA variant should be associated with the disease to the extent predicted by (1) the size of the effect of the variant on the phenotype and (2) the size of the effect of the phenotype on the disease (Fig. 8-11). If the predicted association between the variant and disease was not observed in an adequately powered sample, it would argue against a purely causal role for the intermediate phenotype in pathogenesis of the disease.

The study design is akin to a prospective randomized clinical trial in that randomization for each individual occurs at the moment of

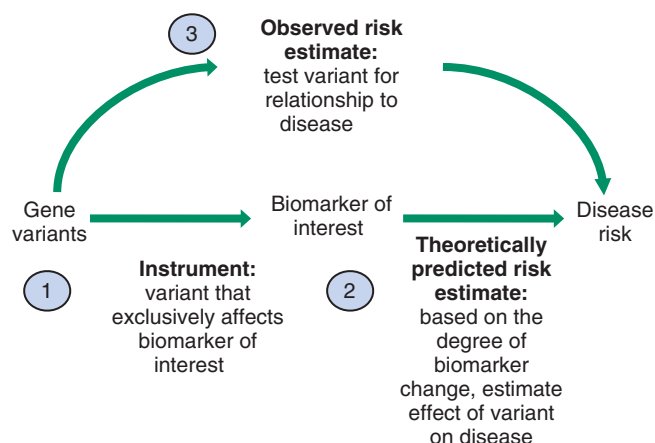

FIGURE 8-11 Design of a mendelian randomization study to test whether a biomarker causally influences risk for disease. The study design has three elements. First, one needs to identify a genetic variant, an instrument that exclusively alters the biomarker of interest. Second, one needs to derive a theoretically predicted estimate of disease risk for the instrument. This estimate is usually derived on the basis of (1) association of the gene variant to the biomarker (i.e., the degree of change in the biomarker conferred by the variant) and (2) association of the biomarker to disease in the population (i.e., the extent to which a given change in biomarker is expected to alter risk for disease in the population). Finally, one derives an observed disease risk estimate for the instrument after testing the instrument for association with disease in the population. If the observed risk estimate for the instrument is consistent with that predicted theoretically, this supports the notion that the biomarker causally influences risk for disease.

conception—genotypes of DNA variants are randomly “assigned” to gametes during meiosis, a process that should be impervious to the typical confounders observed in observational epidemiologic studies. For example, a parent’s disease status or socioeconomic status should not affect which of the parent’s two alleles at a given SNP is passed to a child, with each allele having an equal (50%) chance of being transmitted via the gamete to the zygote. Thus mendelian randomization should be unaffected by confounding or reverse causation. Mendelian randomization has potential shortcomings, however, including that (1) the technique is only as reliable as the robustness of the estimates of the effect sizes of the variant on the phenotype and of the phenotype on disease, and that (2) it assumes that the DNA variant does not influence the disease by means other than the intermediate phenotype being studied (pleiotropy), which may not be true. In addition, a potential confounder of mendelian randomization is that, in certain situations, a disease might cause the allele of a DNA variant passed from a parent to an offspring to be expressed in a different way; for example, it could occur through inherited epigenetic effects. Nevertheless, mendelian randomization has the potential to be as informative as a traditional randomized clinical trial.

Several mendelian randomization studies have confirmed a causal relationship between LDL-C and CHD. Nonsense variants in the *PCSK9* gene that significantly reduce plasma LDL-C concentrations have been associated with a reduced incidence of CHD in a black cohort.²⁴ Similarly, in white subjects a low-frequency missense variant in *PCSK9* was found to be associated with lower LDL-C levels, as well as with a lower risk for MI. These observations suggest that lower LDL-C is sufficient to provide protection against CHD. Similar to LDL-C, several recent genetic studies have confirmed previous observations that plasma lipoprotein(a) (Lp[a]) is causally related to CHD.^{33,34}

Unlike the results with plasma LDL-C and Lp(a) concentrations, a recent large mendelian randomization study of variants that affect plasma HDL-C, performed in more than 100,000 individuals, did not show an association between these variants and MI.³⁵ The investigators performed two mendelian randomization analyses. First, an SNP in the endothelial lipase gene (*LIPG* Asn396Ser) was used as an instrument, and this SNP was tested in 20 studies (20,913 MI cases, 95,407 controls). Second, a genetic score consisting of 14 common

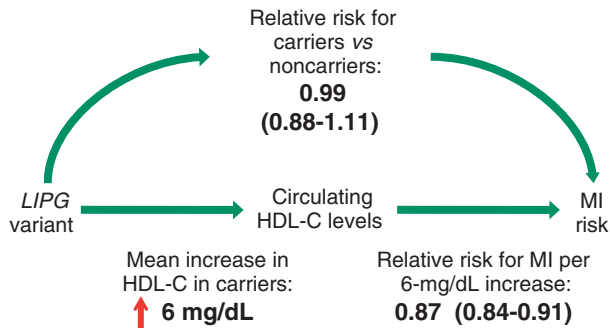

FIGURE 8-12 Mendelian randomization study for plasma HDL-C and risk for MI by using an instrument in the endothelial lipase (*LIPG*) gene. Individuals who carry the serine allele at amino acid 396 of the *LIPG* gene have about 6 mg/dL higher HDL-C. If HDL-C were a causal factor, carriers of the serine allele would be expected to be protected from risk for MI. After association testing in 116,320 individuals, the *LIPG* instrument was not associated with MI. Individuals who carried the HDL-boosting variants had the same risk for MI as did those who did not carry the variant.

SNPs that are exclusively associated with HDL-C was used as an instrument, and this score was tested in up to 12,482 MI cases and 41,331 controls. As a positive control, the investigators tested a genetic score of 13 common SNPs exclusively associated with LDL-C. Carriers of the *LIPG* 396Ser allele (2.6% frequency) had higher HDL-C (5.5 mg/dL higher, $P = 8 \times 10^{-13}$) but similar levels of other lipid and nonlipid risk factors for MI when compared with noncarriers. This difference in HDL-C was expected to decrease the risk for MI by 13% (odds ratio [OR], 0.87; 95% confidence interval [CI], 0.84 to 0.91), but the 396Ser allele was not associated with risk for MI (OR, 0.99; 95% CI, 0.88 to 1.11, $P = 0.85$) (Fig. 8-12). From observational epidemiology, an increase of 1 standard deviation (SD) in HDL-C is associated with a reduced risk for MI (OR, 0.62; 95% CI, 0.58 to 0.66). A 1-SD increase in HDL-C because of genetic score, however, was not associated with risk for MI (OR, 0.93; 95% CI, 0.68 to 1.26, $P = 0.63$). For LDL-C, the estimate from observational epidemiology (a 1-SD increase in LDL-C is associated with risk for MI; OR, 1.54; 95% CI, 1.45 to 1.63) agreed with that from the genetic score (OR, 2.13; 95% CI, 1.69 to 2.69, $P = 2 \times 10^{-10}$). The authors interpreted these findings as indicating that some genetic mechanisms that raise plasma HDL-C do not seem to lower the risk for MI. These data challenge the concept that raising plasma HDL-C therapeutically will uniformly translate into reductions in risk for MI.

A parallel line of clinical trial evidence also casts doubt on the notion that *any* intervention that raises HDL-C will reduce risk for MI. Dalcetrapib, an inhibitor of cholesterol ester transfer protein (CETP), raised HDL-C by approximately 30% in comparison to placebo. As a result, the dal-OUTCOMES trial randomly assigned more than 15,000 participants to test the hypothesis that CETP inhibition with dalcetrapib will reduce cardiovascular morbidity and mortality in patients with a recent acute coronary syndrome.³⁶ In May 2012, the data safety and monitoring board stopped the trial at a second interim analysis because of “lack of clinically meaningful efficacy” (see also Chapters 42 and 45). When combined, the dalcetrapib clinical trial results and the human genetic findings summarized here cast doubt on the notion that raising HDL-C in isolation will reduce risk for CHD. For several decades the biomedical research community has assumed that if an intervention raises HDL-C, that intervention will reduce risk for CHD. It seems prudent now to rethink this assumption and reevaluate the use of HDL-C as a biomarker predictive of CHD in intervention studies.

Overall, with the recent explosion in our ability to measure soluble biomarkers (including metabolites and proteins, see Chapter 10) and genetic variation, mendelian randomization will probably be used increasingly to distinguish causal biomarkers from noncausal ones.

Personalized Medicine

PATIENT CASE, PART V. Shortly after his clinic visit, the 43-year-old brother (KS) goes to the emergency department because of

severe chest pain. He is found to be in the throes of STEMI. The cardiac catheterization team is activated to perform a percutaneous coronary intervention. The emergency department physician asks the cardiology consultant which antiplatelet agent besides aspirin should be administered to the patient at this time.

Just as genetic data can be used to predict a patient's risk for development of a disease, it can also be used to predict whether a patient will have a therapeutic response and/or an adverse response to a particular medication. Termed pharmacogenetics or, in broader terms, personalized medicine, its goal is to safely deliver the right therapy at the right dose to the right patient (see also Chapters 7 and 9).

One example of the emerging use of pharmacogenetics centers on use of the antiplatelet agent clopidogrel. Given routinely to patients after a coronary event, clopidogrel has reduced the risk for future coronary events and, in patients in whom coronary stents are placed, has decreased the risk for in-stent thrombosis. Common loss-of-function variants in the *CYP2C19* gene, which encodes an enzyme that metabolizes clopidogrel into its active form, have been shown to reduce the effectiveness of the medication, especially with respect to the prevention of in-stent thrombosis.^{37,38} Accordingly, many institutions are evaluating whether *CYP2C19* genotyping should be performed at the point of care and used to guide the choice of therapy. Alternatives for patients found to have loss-of-function *CYP2C19* variants might be prescription of an increased dose of clopidogrel or the use of an alternative medication of the same drug class, such as prasugrel or ticagrelor, that *CYP2C19* function does not affect.

Therapeutic Targets: From Gene to Drug in a Decade

The example of *PCSK9* has emerged as a success story for the translation of cardiovascular genetics to the clinic in a relatively short time. The original report of the involvement of gain-of-function mutations in *PCSK9* in causing FH was published in 2003. Just 10 years later, several companies have developed antibody-based drugs targeting the PCSK9 protein that are being evaluated in clinical trials.^{39,40} Development of these drugs was directly motivated by the finding that individuals with loss-of-function *PCSK9* mutations are genetically protected from CHD without suffering any known ill effects. Preliminary data from the clinical trials have demonstrated a large reduction in blood LDL-C levels with these agents, in some cases surpassing even the most potent statin drugs. Although the cholesterol-lowering effects of these agents are expected to result in a reduction in cardiovascular risk, definitive outcomes trials remain to be completed.

FUTURE DIRECTIONS

The last decade has witnessed remarkable advances in human genetics that have the promise of transforming our understanding of cardiovascular disease, as well as the approaches by which practitioners will prevent and treat disease. Although we are still largely in an information-gathering stage, the first practical applications of the information have begun to emerge—ranging from improvement in cardiovascular risk prediction, to the use of pharmacogenetics to tailor therapy for individual patients, to the development of novel therapies such as the PCSK9 antibody-based drugs. In the decade to come, we can expect substantial progress in all these domains.

Indeed, not too far in the future, the standard of cardiovascular care may look quite different from today's practices. Patients would undergo whole-genome sequencing at birth, thereby allowing so-called primordial prevention by assessing the genetic determinants of an individual's lifetime risk for cardiovascular disease and institution of appropriate counseling—starting with life-long exercise and dietary habits and, as the patient advances in age, individually tailored preventive medications and therapies that address all the individual's various validated, causal genetic risk factors for disease. If cardiovascular disease should nevertheless emerge at some point in the patient's life, he or she would receive the specific therapies that

have been demonstrated to be most efficacious and safest for individuals with that genetic profile, both in the acute setting and in the long term for secondary prevention. This standard of care would represent an important step toward ensuring that people everywhere enjoy longer lives free of cardiovascular disease.

IMPORTANCE OF CORRECT DRUG USE

Drug treatment makes up a large fraction of total health care costs. In 2008, the total cost of healthcare in the United States was approximately \$2.5 trillion, and more than 10% was spent on prescription drugs.¹ Cardiovascular disease makes up the largest subcategory in this spending: The American Heart Association estimated that the 2008 cost of care for cardiovascular disease was \$298 billion, and total prescription drug costs for cardiovascular care were \$33 billion.²

Patients vary in their responses to drug treatment, and multiple mechanisms can be invoked, such as poor compliance, variable impact of diverse disease mechanisms on drug actions, drug interactions, and an increasingly recognized role of genomic variation. Indeed, adverse drug reactions across all therapeutic categories are estimated to be the fourth to the sixth most common cause of death in the United States, costing \$19 to \$27 billion annually, and accounting directly for 3% to 6% of all hospital admissions.³ This chapter outlines principles of drug action, the major mechanisms underlying variability in drug effects, and current and future approaches to enable the safest and most effective therapy for an individual patient.

THE KEY DECISION IN DRUG THERAPY: RISK VERSUS BENEFIT

The fundamental assumption underlying administration of any drug is that the real or expected benefit exceeds the anticipated risk. The benefits of drug therapy are initially defined in small clinical trials, perhaps involving several thousand patients, before a drug's marketing and approval. Ultimately, the efficacy and safety profiles of any drug are determined after the compound has been marketed and used widely in hundreds of thousands of patients.

When a drug is administered for the acute correction of a life-threatening condition, the benefits are often self-evident; insulin for diabetic ketoacidosis, nitroprusside for hypertensive encephalopathy, and lidocaine for ventricular tachycardia are examples. Extrapolation of such immediately obvious benefits to other clinical situations may not be warranted, however.

The efficacy of lidocaine to terminate ventricular tachycardia led to its widespread use as a prophylactic agent in cases of acute myocardial infarction, until it was recognized that in this setting, the drug does not alter mortality rates. The outcome of the Cardiac Arrhythmia Suppression Trial (CAST) highlights the difficulties in extrapolating from an incomplete understanding of physiology to chronic drug therapy. CAST tested the hypothesis that suppression of ventricular ectopic activity, a recognized risk factor for sudden death after myocardial infarction, would reduce mortality; this notion was highly ingrained in cardiovascular practice in the 1970s and 1980s. In CAST,

sodium channel-blocking antiarrhythmics did suppress ventricular ectopic beats but also unexpectedly increased mortality threefold. Similarly, with the development of a first-generation cholesterol ester transport protein (CETP) inhibitor, the goal of elevation of high-density lipoprotein (HDL) levels was achieved, but with an accompanying increase in mortality. Thus, the use of arrhythmia suppression or of HDL elevation as a surrogate marker did not produce the desired drug action, reduction in mortality, probably because the underlying pathophysiology or full range of drug actions were incompletely understood.

Similarly, drugs with positive inotropic activity augment cardiac output in patients with heart failure but also are associated with an increase in mortality, probably as a consequence of drug-induced arrhythmias. Nevertheless, clinical trials with these agents suggest symptom relief. Thus, the prescriber and the patient may elect therapy with positive inotropic drugs to realize this benefit while recognizing the risk. This complex decision making is at the heart of the broad concept of personalized medicine that incorporates into the care of an individual patient not only genomic (or other) markers of variable drug responses but also factors such as patients' understanding of their disease and their willingness to tolerate minor or serious risks of treatment.

The risks of drug therapy may be a direct extension of the pharmacologic actions for which the drug is actually being prescribed. Excessive hypotension in a patient taking an antihypertensive agent and bleeding in a patient taking a platelet IIb/IIIa receptor antagonist are examples. In other cases, adverse effects develop as a consequence of pharmacologic actions that were not appreciated during a drug's initial development and use in patients. Rhabdomyolysis occurring with HMG-CoA reductase inhibitors (statins), angioedema developing during ACE inhibitor therapy, and torsades de pointes arising during treatment with noncardiovascular drugs such as thioridazine or pentamidine are examples. Of importance, these rarer but serious effects generally become evident only after a drug has been marketed and extensively used. Even rare adverse effects can alter the overall perception of risk versus benefit and can prompt removal of the drug from the market, particularly if alternate therapies thought to be safer are available. For example, withdrawal of the first insulin sensitizer, troglitazone, after recognition of hepatotoxicity was further spurred by the availability of other new drugs in this class.

The recognition of multiple cyclooxygenase (COX) isoforms led to the development of specific COX-2 inhibitors to retain aspirin's analgesic effects but reduce gastrointestinal side effects. However, one of these, rofecoxib, was withdrawn because of an apparent increase in cardiovascular mortality. The events surrounding the withdrawal of rofecoxib have important implications for drug development and utilization. First, specificity achieved by targeting a single molecular entity may not necessarily reduce adverse effects; one possibility is

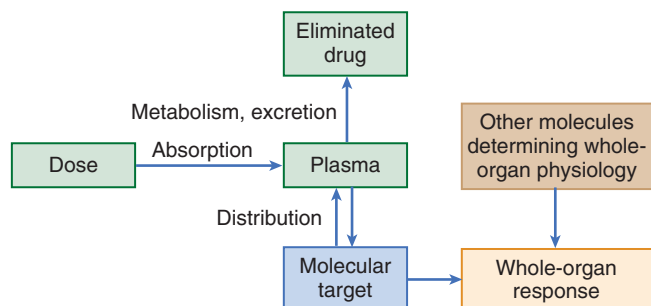

FIGURE 9-1 A model for understanding variability in drug action. When a dose of a drug is administered, the processes of absorption, metabolism, excretion, and distribution determine its access to specific molecular targets that mediate beneficial and toxic effects. The interaction between a drug and its molecular target then produces changes in molecular, cellular, whole-organ, and ultimately whole-patient physiology. This molecular interaction does not occur in a vacuum, but rather in a complex biologic milieu modulated by multiple factors, some of which are disturbed to cause disease. DNA variants in the genes responsible for the processes of drug disposition (green), the molecular target (blue), or the molecules determining the biologic context in which the drug-target interaction occurs (brown) all can contribute to variability in drug action.

that by inhibiting COX-2, the drug removes a vascular protective effect of prostacyclin. Second, drug side effects may include not only readily identifiable events such as rhabdomyolysis or torsades de pointes but also an increase that may be difficult to detect in events such as myocardial infarction that are common in the general population.

MECHANISMS UNDERLYING VARIABILITY IN DRUG ACTION

Two major processes determine how the interaction between a drug and its target molecule(s) can generate variable drug actions in a patient (Fig. 9-1). The first, *pharmacokinetics*, describes drug delivery to and removal from the target molecule and includes the processes of absorption, distribution, metabolism, and excretion—collectively termed drug disposition. The second process, *pharmacodynamics*, describes how the interaction between a drug and its molecular target(s) generates downstream molecular, cellular, whole-organ, and whole-body effects.

The framework shown in Figure 9-1 identifies a series of genes that mediate clinical drug actions, and in which variants may thus contribute to variable drug actions. These genes encode drug-metabolizing enzymes, drug transport molecules, drug targets, and molecules modulating the biology in which the drug-target interaction occurs. The latter include molecular perturbations that cause the disease being targeted. *Pharmacogenetics* describes the concept that individual variants in the genes controlling these processes contribute to variable drug actions, whereas *pharmacogenomics* describes the way in which variability across multiple genes, up to whole genomes, explains differences in drug response among individuals and populations. Presented next is an overview of broad principles of pharmacokinetics, pharmacodynamics, and pharmacogenomics, followed by more detailed discussions of the specific genes, their function, and important variants influencing cardiovascular drug responses.

Pharmacokinetic Principles

Administration of an intravenous drug bolus results in maximal drug concentrations at the end of delivery of the bolus, followed by a decline in plasma drug concentrations over time (Fig. 9-2A), generally due to drug elimination. The simplest case is one in which this decline occurs monoexponentially over time. A useful parameter to describe this decline is the half-life ($t_{1/2}$), the time in which 50% of the drug is eliminated; for example, after two half-lives, 75% of the drug has been eliminated; after three half-lives, 87.5%. A monoexponential process can be considered almost complete in four or five half-lives.

In some cases, the decline of drug concentrations following administration of an intravenous bolus dose is multiexponential. The most common explanation is that drug is not only eliminated (represented by the terminal portion of the time-concentration plot) but also

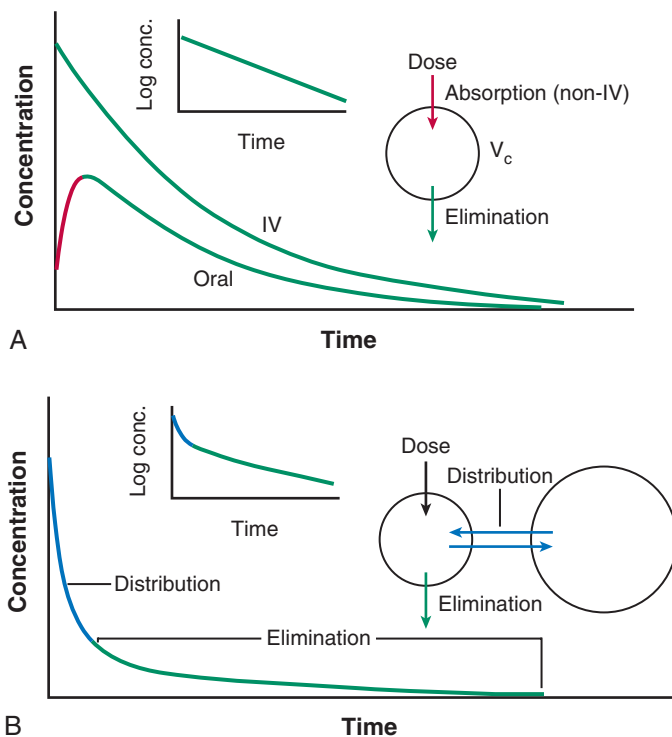

FIGURE 9-2 Models of plasma concentrations as a function of time after a single dose of a drug. **A**, The simplest situation is one in which a drug is administered as a rapid intravenous (IV) bolus into a volume (V_c), where it is instantaneously and uniformly distributed. Elimination then takes place from this volume. In this case, drug elimination is monoexponential; that is, a plot of the logarithm of concentration versus time is linear (inset). When the same dose of drug is administered orally, a distinct absorption phase is required before drug entry into V_c . Most absorption (shown here in red) is completed before elimination (shown in green), although the processes overlap. In this example, the amount of drug delivered by the oral route is less than that delivered by the intravenous route, assessed by the total areas under the two curves, indicating reduced bioavailability. **B**, In this example, drug is delivered to the central volume, from which it is not only eliminated but also undergoes distribution to the peripheral sites. This distribution process (blue) is more rapid than elimination, resulting in a distinct biexponential disappearance curve (inset).

undergoes more rapid distribution to peripheral tissues. Just as elimination may be usefully described by a half-life, distribution half-lives also can be derived from curves such as those shown in Figure 9-2B.

The plasma concentration measured immediately after a bolus dose can be used to derive a volume into which the drug is distributed. When the decline of plasma concentrations is multiexponential, multiple distribution compartments can be defined; these volumes of distribution can be useful in considering dose adjustments in cases of disease but rarely correspond exactly to any physical volume, such as plasma or total body water. With drugs that are highly tissue-bound (e.g., some antidepressants), the volume of distribution can exceed total body volume by orders of magnitude.

Drugs are often administered by nonintravenous routes, such as oral, sublingual, transcutaneous, or intramuscular. Such routes of administration differ from the intravenous route in two ways (see Fig. 9-2A). First, concentrations in plasma demonstrate a distinct rising phase as the drug slowly enters plasma. Second, the total amount of drug that actually enters the systemic circulation may be less than that achieved by the intravenous route. The relative amount of drug entering by any route, compared with the same dose administered intravenously, is termed *bioavailability*. Some drugs undergo such extensive presystemic metabolism that the amount of drug required to achieve a therapeutic effect is much greater (and often more variable) than that required for the same drug administered intravenously. Thus, small doses of intravenous propranolol (5 mg) may achieve heart rate slowing equivalent to that observed with much larger oral doses (80 to 120 mg). Propranolol is actually well absorbed but undergoes extensive metabolism in the intestine and liver before entering the systemic circulation. Another example is that of amiodarone; its physicochemical characteristics make it only 30% to 50% bioavailable when administered orally. Thus, an intravenous infusion of 0.5 mg/min (720 mg/day) is equivalent to 1.5 to 2 g/day orally.

Drug elimination occurs by metabolism followed by the excretion of metabolites and unmetabolized parent drug, generally by the biliary tract or kidneys. This process can be quantified as *clearance*, the volume that is cleared of drug in any given period. Clearance may be organ-specific (e.g., renal clearance, hepatic clearance) or whole-body clearance. Drug metabolism is conventionally divided into phase I oxidation and phase II conjugation, both of which enhance water solubility and, consequently, biliary or renal elimination.

The most common enzyme systems mediating phase I drug metabolism are those of the cytochrome P-450 superfamily, termed CYPs. Multiple CYPs are expressed in human liver and other tissues. A major source of variability in drug action is variability in CYP expression and/or genetic variants that alter CYP activity. **Table 9-1** lists CYPs and other drug-metabolizing enzymes important in cardiovascular therapy. Excretion of drugs or their metabolites into the urine or bile is accomplished by glomerular filtration or specific drug transport molecules, whose level of expression and genetic variation are only now being explored. One widely studied transporter is P-glycoprotein, the product of expression of the *MDR1* (or *ABCB1*) gene. Originally identified as a factor mediating multiple drug resistance in patients with cancer, P-glycoprotein expression is now well recognized in normal enterocytes, hepatocytes, renal tubular cells, the endothelium of the capillaries forming the blood-brain barrier, and the testes. In each of these sites, P-glycoprotein expression is restricted to the apical aspect of polarized cells, where it acts to enhance drug efflux. In the intestine, P-glycoprotein pumps substrates back into the lumen, thereby limiting bioavailability. In the liver and kidney, it promotes drug excretion into bile or urine. In central nervous system capillary endothelium, P-glycoprotein-mediated efflux is an important mechanism limiting drug access to the brain. Drug transporters play a role not only in drug elimination but also in drug uptake into many cells, including hepatocytes and enterocytes.

Pharmacodynamic Principles

Drugs can exert variable effects, even in the absence of pharmacokinetic variability. As indicated in **Figure 9-1**, this can arise as a function of variability in the molecular targets with which drugs interact to achieve their beneficial and adverse effects, as well as variability in the broader biologic context within which the drug-target interaction

takes place. Variability in the number or function of a drug's target molecules can arise because of genetic factors (see later) or because disease alters the number of target molecules or their state (e.g., changes in the extent of phosphorylation). Simple examples of variability in the biologic context are high dietary salt, which can inhibit the antihypertensive action of beta blockers, and hypokalemia, which increases the risk for drug-induced QT prolongation. In addition, disease itself can modulate drug response. For example, the effect of lytic therapy in a patient with no clot is manifestly different from that in a patient with acute coronary thrombosis, or the vasodilating effects of nitrates, beneficial in patients with coronary disease with angina, can be catastrophic in patients with aortic stenosis. These examples highlight the requirement for precision in diagnosis to avoid situations in which risk outweighs potential benefit. One hope is that emerging genomic or other molecular approaches can add to this precision.

The targets with which drugs interact to produce beneficial effects may or may not be the same as those with which drugs interact to produce adverse effects. Drug targets may be in the circulation, at the cell surface, or within cells. Many newer drugs have been developed to interact with a specific drug target; examples of such targets are 3-hydroxy-3-methyl-glutaryl-coenzyme A (HMG-CoA) reductase, angiotensin-converting enzyme (ACE), G protein-coupled receptors (e.g., alpha, beta, angiotensin II, histamine), and platelet IIb/IIIa receptors. Such targets generally are identified in the course of basic mechanistic studies; a very appealing newer approach is to use modern genetic techniques to identify DNA variants associated with desired phenotypes, such as absence of myocardial infarction, as a clue to identify new drug targets.⁴ On the other hand, many drugs widely used in cardiovascular therapeutics were developed when the technology to identify specific molecular targets simply was not available; digoxin, amiodarone, and aspirin are examples. Some, like amiodarone, have many drug targets. In other cases, however, even older drugs turn out to have rather specific molecular targets. The actions of digitalis glycosides are mediated primarily by the inhibition of Na⁺/K⁺-ATPase. Aspirin permanently acetylates a specific serine residue on the COX enzyme, an effect that is thought to mediate its analgesic effects and its gastrointestinal toxicity.

Time Course of Drug Effects

With repeated doses, drug levels accumulate to a *steady state*, the condition under which the rate of drug administration is equal to the rate of drug elimination in any given period. Drug accumulation to steady state is near-complete in four to five elimination half-lives (see **Fig. 9-3**). For many drugs, the target molecule is in or readily accessible from plasma, so this time course also describes the development of pharmacologic effects. However, in other cases, whereas steady-state plasma concentrations are achieved in four to five elimination half-lives, steady-state drug effects take longer to achieve and several explanations are possible. First, an active metabolite may need to be generated to achieve drug effects. Second, time may be required for translation of the drug effect at the molecular site to a physiologic endpoint; inhibition of synthesis of vitamin K-dependent clotting factors by warfarin ultimately leads to a desired elevation of the international normalized ratio (INR), but the development of this desired effect occurs only as levels of clotting factors fall. Third, penetration of a drug into intracellular or other tissue sites of action may be required before development of drug effect. One mechanism underlying such penetration is the variable function of specific drug uptake and efflux transport proteins that control intracellular drug concentrations.

Pharmacogenomic Principles

As described next, studies have exploited a range of experimental techniques to establish a role for both common and rare DNA polymorphisms in pharmacokinetic and pharmacodynamic pathways as mediators of variable drug actions. Rare disease-associated variants are traditionally termed *mutations*, whereas commoner variants (traditionally defined as minor allele frequency >1%) are termed *polymorphisms*. The commonest type is a single-nucleotide polymorphism (SNP); SNPs that change the encoded amino acid are termed

TABLE 9-1 Proteins Important in Drug Metabolism and Elimination

PROTEIN	SUBSTRATES
CYP3A4, CYP3A5	Erythromycin, clarithromycin; quinidine, mexiletine; many benzodiazepines; cyclosporine, tacrolimus; many antiretrovirals; HMG CoA reductase inhibitors (atorvastatin, simvastatin, lovastatin; not pravastatin); many calcium channel blockers
CYP2D6*	Some beta blockers—propranolol, timolol, metoprolol, carvedilol Propafenone; desipramine and other tricyclics; codeine [†] ; tamoxifen [†] ; dextromethorphan
CYP2C9*	Warfarin, phenytoin, tolbutamide, losartan [†]
CYP2C19*	Omeprazole, clopidogrel [†]
P-glycoprotein	Digoxin
N-acetyl transferase*	Procainamide, hydralazine, isoniazid
Thiopurine methyltransferase*	6-Mercaptopurine, azathioprine
Pseudocholinesterase*	Succinylcholine
UDP-glucuronosyltransferase*	Irinotecan [†]
SLCO1B1*	Simvastatin and other statins; methotrexate; troglitazone; bosentan

Full CYP listing is available at <http://medicine.iupui.edu/flockhart>.

*Clinically important genetic variants described; see text.

[†]Prodrug bioactivated by drug metabolism.

nonsynonymous. The advent of modern sequencing technologies has demonstrated that most DNA variants in an individual are in fact rare,⁵ so the distinction between mutation and polymorphism is blurred. Furthermore, polymorphism frequencies can vary strikingly by ethnicity; a common variant in persons of African ethnicities may be absent in whites.

One of the great success stories of modern cardiovascular genetics has been the use of linkage analysis in large families to identify disease-causing rare variants (mutations) in familial syndromes with highly unusual clinical phenotypes, such as familial hypercholesterolemia (see Chapter 45), hypertrophic cardiomyopathy (see Chapter 66), or the ion channelopathies (see Chapter 32). Linkage analysis has not been widely applied to study pharmacogenomics because large kindreds in which multiple individuals display extreme responses to drug exposure generally are not available. In the syndrome of malignant hyperthermia occurring in response to general anesthetics, it was possible to assign phenotype using functional studies in muscle biopsies and thus identify a linkage signal at chromosomal region 19q, which includes the gene encoding RYR1, the skeletal muscle calcium release channel in which mutations cause the disease.

When an extreme phenotype occurs in multiple family members, it is logical to invoke a genetic origin. It is now clear that DNA variation

also contributes importantly to variability in common human traits, such as laboratory values or susceptibility to common disease. Methods are available to establish the extent to which that variability includes a heritable component, generally by examining twins, large families, or groups of families; evidence for heritability provides strong justification for pursuing studies to identify contributing genetic variation. Indeed, this general approach has established that common phenotypes such as LDL cholesterol, blood pressure, or susceptibility to atrial fibrillation are highly heritable. The extent to which rare and common variants contribute to this variability is only now being addressed. Across populations, it is very unusual for single common DNA polymorphisms to account for more than even 1% of variability in common traits. Variability in response to drug exposure presents a striking exception to this general rule, where even single common DNA polymorphisms may contribute substantially, 10% or more in many cases, to overall variability in drug response. It has been speculated that common variants with large effects on drug response can persist in a population because there is no evolutionary pressure against such variants since drug exposure is a recent event in human history. One mechanism accounting for this large effect is common SNPs in drug metabolism pathways that then result in very large fluctuations in drug concentration and corresponding effects. As described further on,

common SNPs in drug target genes also can produce such large effects. Examples of specific cardiovascular phenotypes in which common SNPs have been associated with risk are presented in Table 9-2 and discussed later on. Of note, rarer variants in these (or other) genes are only now being described, so their role in mediating drug response is much less well understood. In addition, virtually all studies to date have focused primarily on white populations, and data are only now being generated on specific polymorphisms mediating variable drug actions in other ancestries.

One technique to identify associations between DNA polymorphisms and drug response (or other) traits uses an understanding of the physiology of the trait under question to identify candidate genes modulating the trait. Thus, for example, an investigator

FIGURE 9-3 Time course of drug concentrations when treatment is started or dose changed. **Left**, The hash lines on the abscissa each indicate one elimination half-life ($t_{1/2}$). With a constant rate intravenous (IV) infusion (gold), plasma concentrations accumulate to steady state in four or five elimination half-lives. When a loading bolus is administered with the maintenance infusion (blue), plasma concentrations are transiently higher but may dip, as shown here, before achieving the same steady state. When the same drug is administered by the oral route, the time course of drug accumulation is identical (magenta); in this case the drug was administered at intervals of 50% of a $t_{1/2}$. Steady-state plasma concentrations during oral therapy fluctuate around the mean determined by intravenous therapy. **Right**, This plot shows that when dosages are doubled, or halved, or the drug is stopped during steady-state administration, the time required to achieve the new steady state is four or five $t_{1/2}$ and is independent of the route of administration.

TABLE 9-2 Examples of Common Single Nucleotide Polymorphisms Mediating Variable Drug Actions

DRUG EFFECT	PATHWAY	GENE	SNP	DBSNP ID NUMBER	COMMENTS
Adverse outcomes during clopidogrel treatment for acute coronary syndrome	PK	CYP2C19	CYP2C19*2: truncation at P227	rs4244285	*2 results in defective clopidogrel bio-activation; this SNP contributes ~10% to variability in clopidogrel-mediated inhibition of ADP-induced platelet aggregation
Excess beta blocker effect: metoprolol, timolol	PK	CYP2D6	Many variants		
Warfarin steady-state dose	PK	CYP2C9	CYP2C9*2: R144C CYP2C9*3: I359L	rs1799853 rs1057910	VKORC1 and CYP2C9 variants account for ~50% of variability in warfarin steady-state dose
	PD	VKORC1	Promoter variant: -1639G>A	rs9923231	
	PD	CYP4F2	V433M	rs2108622	
Statin myotoxicity	PK	SLCO1B1	SLCO1B1*5: V174A	rs4149056	Risk of simvastatin myotoxicity increased 20-fold in homozygotes and 4-fold in heterozygotes
Response to beta blockers for hypertension, heart failure	PD (target)	ADRB1 ADRB2	S49G R389G	rs1801252 rs1801253	
Beta blocker therapy in heart failure	PD (target)	GRK5	G41L	rs17098707	
Antihypertensive response during thiazides	PD	ADD1	G460W	rs4961	
Torsades de pointes	PD	KCNE1	D85N	rs1805128	8% allele frequency in patients with torsades versus ~2% in control subjects (odds ratio ~10)

dbSNP = National Center for Biotechnology Information's SNP database; PD = pharmacodynamic; PK = pharmacokinetic.

interested in variability in the PR interval might invoke polymorphisms in calcium channel genes, or an investigator interested in blood pressure might invoke variation in the ACE gene. The association between polymorphisms in these candidate genes and the phenotype under study is then examined in persons with well-characterized phenotypes. The candidate gene approach is intuitively appealing because it takes advantage of what is known about underlying physiology. Despite this appeal, however, the method is now recognized to carry with it the great potential for false-positive associations, especially when small numbers of subjects are studied. An important exception has been in pharmacogenomics, where the candidate gene approach has yielded important and clinically reproducible associations between single common polymorphisms and drug response. This exception probably reflects the unusually high contribution of SNPs to overall variability in drug response mentioned above.

Another approach to identifying polymorphisms contributing to variable human traits is the genome-wide association study (GWAS). Here, study subjects are genotyped at hundreds of thousands or millions of sites known to harbor common SNPs across the genome. Because the GWAS platforms focus on common SNPs, effect sizes are often small and difficult to identify and validate unless very large numbers of subjects, thousands or more, are studied. In addition, the SNPs associated with the trait usually are not themselves functional but rather serve as markers for loci that harbor truly functional variants. The great advantage of the method is that it makes no assumptions about underlying physiology, and one of its major accomplishments has been to identify entirely new pathways underlying variability in human traits.⁶ The GWAS approach has been applied to study drug response phenotypes⁷ and even in relatively small sets has occasionally been successful in identifying associated common variants. Sometimes these are known from candidate gene studies. In other cases, notably drug hypersensitivity reactions,⁸ GWASs involving even a few dozen cases have identified strong signals that have then been replicated.

The GWAS paradigm is enabled by technology to generate the dense genotype datasets. New technologies being developed to generate other types of high-dimensional data similarly hold the promise of elucidating new biologic pathways in disease and drug response. Rapid, extremely high-throughput and increasingly inexpensive sequencing technologies are detecting rare DNA sequence variants whose contribution to disease is only now being appreciated.⁵ RNA sequencing ("RNA-Seq") using these technologies is replacing microarray analysis as the method of choice for cataloguing RNA transcript profiles and abundance by specific cellular subtype and disease. Advances in mass spectrometry are similarly enabling development of catalogs (proteomic and metabolomic profiling) of all proteins or of small-molecule metabolites of cellular processes, including drug metabolites, by cell and disease. Other sources of high-dimensional data include electronic medical record (EMR) systems, discussed further later on, and high-density digital images. Integrating these diverse data types into a comprehensive picture of the perturbations that result in disease or variable drug responses is the goal of the evolving discipline of systems biology and pharmacology. It has been proposed that future drug development would be better served by a focus on pathways identified by systems approaches rather than single targets.⁹

MOLECULAR AND GENETIC BASIS FOR VARIABLE DRUG RESPONSE

Many factors contribute to variable drug responses—the patient's age, the severity of the disease being treated, presence of disease of excretory organs, drug interactions, and poor compliance, to name but a few. This section describes major pathways leading to variable drug responses.

When a drug is metabolized and excreted by multiple pathways, absence of one of these, because of genetic variants, drug interactions, or dysfunction of excretory organs, generally does not affect drug concentrations or actions. By contrast, if a single pathway plays a critical role, the drug is more likely to exhibit marked variability in plasma concentration and associated effects, a situation that has been termed high-risk pharmacokinetics.¹⁰

One high-risk scenario is that involving bioactivation of a drug—that is, metabolism of the drug to active and potent metabolites that mediate pharmacologic action. Decreased function of such a pathway reduces or eliminates drug effect. Bioactivation of clopidogrel by

CYP2C19 is an example; persons with reduced CYP2C19 activity (caused by genetic variants or possibly by interacting drugs; see [Tables 9-1](#) and [9-2](#)) have an increased incidence of cardiovascular events following coronary stent placement.¹¹ Similarly, the widely used analgesic codeine undergoes CYP2D6-mediated bioactivation to an active metabolite, morphine, and patients with reduced CYP2D6 activity display reduced analgesia. A small group of individuals with multiple functional copies of *CYP2D6*, and hence increased enzymatic activity, has been identified; in this group, codeine may produce nausea and euphoria, presumably because of rapid morphine generation. A third example is the angiotensin receptor blocker losartan, which is bioactivated by CYP2C9; reduced antihypertensive effect is a risk with common genetic variants that reduce CYP2C9 activity or with coadministration of CYP2C9 inhibitors, such as phenytoin.

A second high-risk pharmacokinetic scenario is one in which a drug is eliminated by only a single pathway. In this case, absence of activity of that pathway will lead to marked accumulation of drug in plasma, and for many drugs, such accumulation results in a high risk of drug toxicity. A simple example is the dependence of sotalol or dofetilide elimination on renal function; failure to decrease the dosage in a patient with renal dysfunction leads to accumulation of these drugs in plasma and an increased risk for drug-induced QT prolongation and torsades de pointes. Similarly, administration of a wide range of P-glycoprotein inhibitors will predictably elevate plasma concentration of digoxin, which is eliminated primarily by P-glycoprotein-mediated efflux into bile and urine (see [Table 9-2](#)).

Administration of CYP2D6-metabolized beta blockers, including metoprolol and carvedilol, to patients with defective enzyme activity may produce exaggerated heart rate slowing. The weak beta-blocking actions of the antiarrhythmic propafenone also are increased in patients with reduced CYP2D6 activity. Some antidepressants are CYP2D6 substrates; for these drugs, cardiovascular adverse effects are more common in poor metabolizers (PMs) of CYP2D6, whereas therapeutic efficacy is more difficult to achieve in ultrarapid metabolizers.

The risk of aberrant drug responses due to CYP variants is greatest in persons who are homozygous (i.e., PMs). However, for drugs with very narrow therapeutic margins (e.g., warfarin, clopidogrel), even heterozygotes may display unusual drug sensitivity. Although PMs make up a minority of subjects in most populations, many drugs in common use can inhibit these enzymes (see [Table 9-3](#)) and thereby "phenocopy" the PM trait. Omeprazole and possibly other proton pump inhibitors block CYP2C19 and have been associated with an increase in cardiovascular events during clopidogrel therapy.¹² Similarly, specific inhibitors of CYP2D6 and CYP2C9 can phenocopy the PM trait when coadministered with substrate drugs ([Table 9-3](#)).

An example of variant drug transporter function mediating variable drug actions is provided by *SLCO1B1*, encoding a drug uptake transporter in liver. A common nonsynonymous SNP in this gene has been associated by candidate studies with variability in simvastatin pharmacokinetics and by GWASs with a markedly increased risk for simvastatin-induced myopathy.¹³

The heart rate slowing and blood pressure effects of beta blockers and beta agonists have been associated with polymorphisms in the *drug targets*, the beta-1 and beta-2 receptors. A common variant in *ADRB1*, encoding the beta-1 receptor, has been implicated as a mediator of survival during therapy with the beta blocker bucindolol in heart failure. Variability in warfarin dose requirements has been clearly associated with variants in both CYP2C9, which mediates elimination of the active enantiomer of the drug, and VKORC1, part of the vitamin K complex that is the drug target. Indeed, these common variants account for up to half of the variability in warfarin dose requirement,¹⁴ illustrating the large impact that common SNPs can exert on drug response phenotypes. Furthermore, allele frequencies vary strikingly by ancestry, probably accounting for the fact that warfarin dose requirements are low in Asian subjects and high in African subjects compared with whites.¹⁵

An example of a variant modulating biologic context in which the drug acts is susceptibility to stroke in patients receiving diuretics; this has been linked to a polymorphism in the alpha-adducing gene whose product plays a role in renal tubular sodium transport.

**TABLE 9-3 Drug Interactions: Mechanisms and Examples**

MECHANISM	DRUG	INTERACTING DRUG	EFFECT
Decreased bioavailability	Digoxin	Antacids	Decreased digoxin effect secondary to decreased absorption
Increased bioavailability	Digoxin	Antibiotics	By eliminating gut flora that metabolize digoxin, some antibiotics may increase digoxin bioavailability; NOTE: some antibiotics also interfere with P-glycoprotein (expressed in the intestine and elsewhere), another effect that can elevate digoxin concentration
Induction of hepatic metabolism	CYP3A substrates: Quinidine Mexiletine Verapamil Cyclosporine	Phenytoin Rifampin Barbiturates St. John's wort	Loss of drug effect secondary to increased metabolism
Inhibition of hepatic metabolism	CYP2C9: Warfarin Losartan	Amiodarone Phenytoin	Decreased warfarin requirement Diminished conversion of losartan to its active metabolite, with decreased antihypertensive control
	CYP3A substrates: Quinidine Cyclosporine HMG-CoA reductase inhibitors: lovastatin, simvastatin, atorvastatin; not pravastatin cisapride, terfenadine, astemizole	Ketoconazole Itraconazole Erythromycin Clarithromycin Some calcium blockers Some HIV protease inhibitors (especially ritonavir)	Increased risk for drug toxicity
	CYP2D6 substrates: Beta blockers (see Table 9-2) Propafenone Desipramine Codeine	Quinidine (even ultralow dose) fluoxetine, paroxetine	Increased beta blockade Increased beta blockade Increased adverse effects Decreased analgesia (due to failure of biotransformation to the active metabolite morphine)
	CYP2C19: Clopidogrel	Omeprazole, possibly other proton pump inhibitors	Decreased clopidogrel efficacy
Inhibition of drug transport	<i>P-glycoprotein transport:</i> Digoxin	Amiodarone, quinidine verapamil, cyclosporine itraconazole, erythromycin	Digoxin toxicity
	<i>Renal tubular transport:</i> dofetilide	Verapamil	Slightly increased plasma concentration and QT effect
	<i>Monoamine transport:</i> guanadrel	Tricyclic antidepressants	Blunted antihypertensive effects
Pharmacodynamic interactions	Aspirin + warfarin		Increased therapeutic antithrombotic effect; increased risk of bleeding
	Nonsteroidal anti-inflammatory drugs	Warfarin	Increased risk of gastrointestinal bleeding
	Antihypertensive drugs	Nonsteroidal anti-inflammatory drugs	Loss of blood pressure lowering
	QT-prolonging antiarrhythmics	Diuretics	Increased torsades de pointes risk secondary to diuretic-induced hypokalemia
	Supplemental potassium	ACE inhibitors	Hyperkalemia
	Sildenafil	Nitrates	Increased and persistent vasodilation; risk of myocardial ischemia

Torsades de pointes during QT-prolonging drug therapy has been linked to polymorphisms not only in the ion channel that is the drug target but to other ion-channel genes; a large candidate gene survey reported that a nonsynonymous SNP in KCNE1, a subunit for the slowly-activating potassium current I_{Ks} , conferred an odds ratio of approximately 10 for torsades risk.¹⁶ In addition, this adverse effect sometimes occurs in patients with clinically latent congenital long-QT syndrome, emphasizing the interrelationship among disease, genetic background, and drug therapy (see Chapters 32 and 35). Drugs also can bring out latent Brugada syndrome (see www.brugadadrugs.org).

The anticancer drug trastuzumab is effective only in patients with cancers that do not express the Her2/neu receptor. Because the drug also potentiates anthracycline-related cardiotoxicity, toxic therapy can be avoided in patients who are receptor-negative (see Chapter 85).

OPTIMIZING DRUG DOSES

The goals of drug therapy should be defined before the initiation of drug treatment. These may include acute correction of serious pathophysiology, acute or chronic symptom relief, or changes in surrogate endpoints (e.g., blood pressure, serum cholesterol, international normalized ratio [INR]) that have been linked to beneficial outcomes in target patient populations. The lessons of CAST and of positive inotropic drugs should make prescribers skeptical about such surrogate-guided therapy in the absence of controlled clinical trials.

When the goal of drug therapy is to acutely correct a disturbance in physiology, the drug should be administered intravenously in doses designed to achieve a therapeutic effect rapidly. This approach is best justified when benefits clearly outweigh risks. Large intravenous drug boluses carry with them a risk of enhancing drug-related toxicity; therefore, even with the most urgent of medical indications, this

approach is rarely appropriate. An exception is adenosine, which must be administered as a rapidly delivered bolus because it undergoes extensive and rapid elimination from plasma by uptake into almost all cells. As a consequence, a slow bolus or infusion rarely achieves sufficiently high concentrations at the desired site of action (the coronary artery perfusing the atrioventricular node) to terminate arrhythmias. Similarly, the time course of anesthesia depends on anesthetic drug delivery to and removal from sites in the central nervous system.

The time required to achieve steady-state plasma concentrations is determined by the elimination half-life (see earlier). The administration of a loading dose may shorten this time, but only if the kinetics of distribution and elimination are known beforehand in an individual subject and the correct loading regimen is chosen. Otherwise, overshoot or undershoot during the loading phase may occur (see Fig. 9-3). Thus, the initiation of drug therapy by a loading strategy should be used only when the indication is acute.

Two dose-response curves describe the relationship between drug dose and the expected cumulative incidence of a beneficial effect or an adverse effect (Fig. 9-4). The distance along the x-axis describing the difference between these curves, often termed the *therapeutic ratio* (or index or window), provides an index of the likelihood that a chronic dosing regimen that provides benefits without adverse effects can be identified. Drugs with especially wide therapeutic indices often can be administered at infrequent intervals, even if they are rapidly eliminated (see Fig. 9-4A, C).

When anticipated adverse effects are serious, the most appropriate treatment strategy is to start at low doses and reevaluate the necessity for increasing drug dosages once steady-state drug effects have been achieved. This approach has the advantage of minimizing the risk of dose-related adverse effects but carries with it a need to titrate doses to efficacy. Only when stable drug effects are achieved should increasing drug dosage to achieve the desired therapeutic effect be considered. An example is sotalol: Because the risk of torsades de pointes increases with drug dosage, the starting dose should be low.

In other cases, anticipated toxicity is relatively mild and manageable. It may then be acceptable to start at dosages higher than the minimum required to achieve a therapeutic effect, accepting a greater than minimal risk of adverse effects; some antihypertensives can be administered in this fashion. However, the principle of using the lowest dose possible to minimize toxicity, particularly toxicity that is unpredictable and unrelated to recognized pharmacologic actions, should be the rule.

Occasionally, dose escalation into the high therapeutic range results in no beneficial drug effect and no side effects. In this circumstance, the prescriber should be alert to the possibility of noncompliance or drug interactions at the pharmacokinetic or pharmacodynamic level. Depending on the nature of the anticipated toxicity, dose escalation beyond the usual therapeutic range may occasionally be acceptable, but only if anticipated toxicity is not serious and is readily manageable.

Plasma Concentration Monitoring

For some drugs, curves such as those shown in Figure 9-4A and B relating drug concentration to cumulative incidence of beneficial and adverse effects can be generated. With such drugs, monitoring plasma

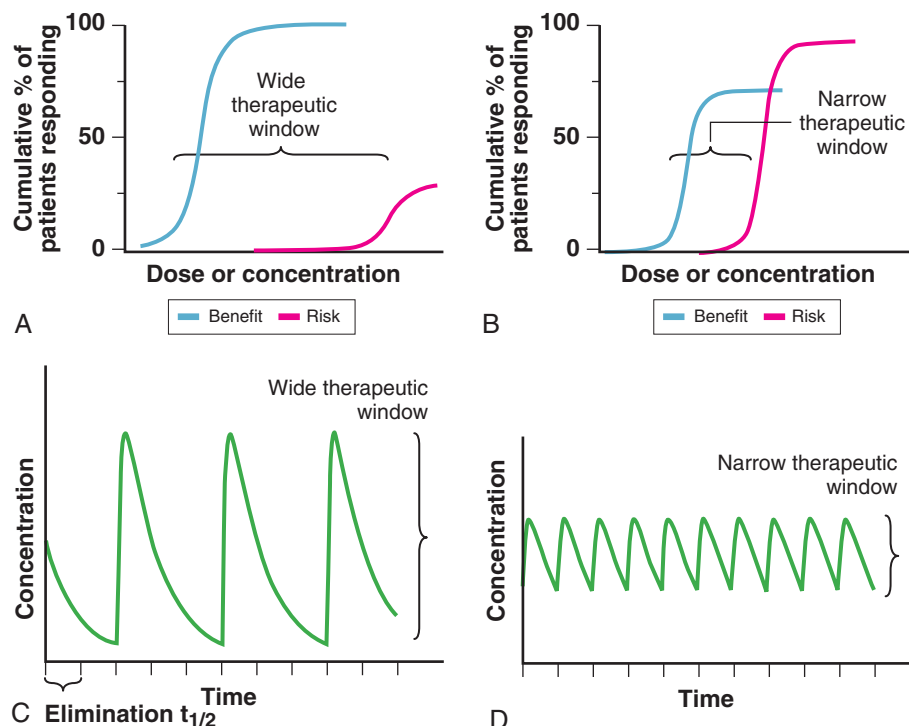

FIGURE 9-4 The concept of therapeutic ratio. **A, B**, Two dose- (or concentration-) response curves. The blue lines describe the relationship between dose and cumulative incidence of beneficial effects, and the magenta line depicts the relationship between dose and dose-related adverse effects (risk). As depicted in **A**, a drug with a wide therapeutic ratio displays separation between the two curves, a high degree of efficacy, and low degree of dose-related toxicity. Under these conditions, a wide therapeutic ratio can be defined. In **B**, conversely, the curves describing cumulative efficacy and cumulative incidence of adverse effects are positioned near each other, the incidence of adverse effects is higher, and the expected beneficial response is lower. These characteristics define a narrow therapeutic ratio. **C, D**, Steady-state plasma concentrations with oral drug administration as a function of time with wide (left) and narrow (right) therapeutic ratios. The hash marks on the abscissae each indicate one elimination half-life. **C**, When the therapeutic window is wide, drug administration every three elimination half-lives can produce plasma concentrations that are maintained above the minimum for efficacy and below the maximum beyond which toxicity is anticipated. **D**, The opposite situation is illustrated. To maintain plasma concentrations within the narrow therapeutic range, the drug must be administered more frequently.

drug concentrations to ensure that they remain within a desired therapeutic range (i.e., above a minimum required for efficacy and below a maximum likely to produce adverse effects) may be a useful adjunct to therapy. Monitoring drug concentrations also may be useful to ensure compliance and to detect pharmacokinetically based drug interactions that underlie unanticipated efficacy and/or toxicity at usual dosages. Samples for measurement of plasma concentrations generally should be obtained just before the next dose, at steady state. These trough concentrations provide an index of the minimum plasma concentration expected during a dosing interval.

On the other hand, patient monitoring, whether by plasma concentration or other physiologic indices, to detect incipient toxicity is best accomplished at the time of anticipated peak drug concentrations. Thus, patient surveillance for QT prolongation during therapy with sotalol or dofetilide is best timed for 1 to 2 hours after the administration of a dose of drug at a steady state.

A lag between the time courses of drug in plasma and drug effects may exist (see earlier). In addition, monitoring plasma drug concentrations relies on the assumption that the concentration measured is in equilibrium with that at the target molecular site. Of note, it is only the fraction of drug not bound to plasma proteins that is available to achieve such equilibration. Variability in the extent of protein binding can therefore affect the free fraction and anticipated drug effect, even in the presence of apparently therapeutic total plasma drug concentrations. Basic drugs such as lidocaine and quinidine are not only bound to albumin but also bind extensively to alpha-1 acid glycoprotein, an acute-phase reactant whose concentrations are increased in a variety of stress situations, including acute myocardial infarction. Because of this increased protein binding, drug effects may be blunted, despite achieving therapeutic total drug concentrations in these situations.

Dose Adjustments Disease and Concomitant Drugs

Polypharmacy is common in patients with varying degrees of specific organ dysfunction. Although treatment with an individual agent may be justified, the practitioner should also recognize the risk of unanticipated drug effects, particularly drug toxicity, during therapy with multiple drugs.

The presence of renal disease mandates dose reductions for drugs eliminated primarily by renal excretion, including digoxin, dofetilide, and sotalol. A requirement for dose adjustment in cases of mild renal dysfunction is dictated by available clinical data and the likelihood of serious toxicity if drug accumulates in plasma because of impaired elimination. Renal failure reduces the protein binding of some drugs (e.g., phenytoin); in this case, a total drug concentration value in the therapeutic range may actually represent a toxic value of unbound drug.

Advanced liver disease is characterized by decreased hepatic drug metabolism and portacaval shunts that decrease clearance, particularly first-pass clearance. Moreover, affected patients frequently have other profound disturbances of homeostasis, such as coagulopathy, severe ascites, and altered mental status. These pathophysiologic features of advanced liver disease can profoundly affect not only the dose of a drug required to achieve a potentially therapeutic effect but also the perception of risks and benefits, thereby altering the prescriber's assessment of the actual need for therapy.

Heart disease similarly carries with it a number of disturbances of drug elimination and drug sensitivity that may alter the therapeutic doses or the practitioner's perception of the desirability of therapy on the basis of evaluation of risks and benefits. Patients with left ventricular hypertrophy often have baseline QT prolongation, so risks associated with use of QT-prolonging antiarrhythmics may increase; most guidelines suggest avoiding QT-prolonging antiarrhythmics in such patients (see [Chapters 35, 86, and 88](#); see also www.torsades.org).

In heart failure (see [Chapter 25](#)), hepatic congestion can lead to decreased clearance with a corresponding increased risk for toxicity with usual doses of certain drugs, including some sedatives, lidocaine, and beta blockers. On the other hand, gut congestion can lead to decreased absorption of orally administered drugs and decreased effects. In addition, patients with heart failure may demonstrate reduced renal perfusion and require dose adjustments on this basis. Heart failure also is characterized by a redistribution of regional blood flow, which can lead to reduced volume of distribution and enhanced risk for drug toxicity. Lidocaine probably is the best-studied example; loading doses of lidocaine should be reduced in patients with heart failure because of altered distribution, whereas maintenance doses should be reduced in heart failure and liver disease because of altered clearance.

Age also is a major factor in determining drug doses, as well as sensitivity to drug effects. Doses in children generally are administered on an mg/kg body weight basis, although firm data to guide therapy are often not available. Variable postnatal maturation of drug disposition systems may present a special problem in the neonate. Older persons often have reduced creatinine clearance, even those with a normal serum creatinine level, and dosages of renally excreted drugs should be adjusted accordingly (see [Chapter 76](#)). Diastolic dysfunction with hepatic congestion is more common in older adults, and vascular disease and dementia are common, which can lead to increased postural hypotension and risk of falling. Therapies such as sedatives, tricyclic antidepressants, or anticoagulants should be initiated only when the practitioner is convinced that the benefits of such therapies outweigh this increased risk.

Drug Interactions

As a result of therapeutic successes not only in heart disease but also in other disease areas, cardiovascular physicians are increasingly encountering patients receiving multiple medications for noncardiovascular indications. [Table 9-3](#) summarizes mechanisms that may underlie important drug interactions. Drug interactions may be based on altered absorption, distribution, metabolism, or excretion. In

addition, drugs can interact at the pharmacodynamic level. A trivial example is the coadministration of two antihypertensive drugs, leading to excessive hypotension. Similarly, coadministration of aspirin and warfarin leads to an increased risk for bleeding, although benefits of the combination also can be demonstrated.

The most important principle in approaching a patient receiving polypharmacy is to recognize the high potential for drug interactions. A complete medication history should be obtained from each patient at regular intervals; patients will often omit topical medications such as eye drops, health food supplements, and medications prescribed by other practitioners unless specifically prompted. Each of these, however, carries a risk of important systemic drug actions and interactions. Even high dosages of grapefruit juice, which contains CYP3A and P-glycoprotein inhibitors, can affect drug responses. Beta blocker eye drops can produce systemic beta blockade, particularly with CYP2D6 substrates (e.g., timolol) in patients with defective CYP2D6 activity. St. John's wort induces CYP3A and P-glycoprotein activity (like phenytoin and other drugs) and thus can markedly lower plasma concentrations of substrate drugs such as cyclosporine. As with many other interactions, this may not be a special problem so long as both drugs are continued. However, if a patient stabilized on cyclosporine stops taking a concomitantly administered CYP3A inducer, plasma concentrations of the drug can rise dramatically and toxicity can ensue. Similarly, initiation of an inducer may lead to markedly lowered cyclosporine concentrations and a risk of organ rejection. A number of natural supplements have been associated with serious drug toxicity that has resulted in withdrawal from the market; phenylpropanolamine-associated stroke is an example.

Incorporating Pharmacogenetic Information into Prescribing

The identification of polymorphisms associated with variable drug responses naturally raises the question of how these data could or should be used to optimize drug doses, to avoid drugs likely to be ineffective, and to avoid drugs likely to produce major toxicities. Indeed, in 2007, the U.S. Food and Drug Administration (FDA) began systematically including pharmacogenetic information in drug labels.¹⁷ Despite the intuitive appeal of a pharmacogenetically guided approach to drug therapy, however, practitioners wishing to adopt genetic testing to guide drug therapy encounter substantial practical barriers; these include cost, varying levels of evidence supporting a role for genetics, and implementation issues such as how fast and accurately a genetic test result can be delivered. It is the nature of pharmacogenetic variation that most patients will display average responses to most drugs, so systematically testing every patient in the hopes of finding the minority likely to display aberrant responses is cumbersome and seems time- and cost-inefficient unless the benefit for individual patients is large. An example of a large benefit is that routine genotyping of all patients receiving the antiretroviral agent abacavir is now standard of care because it avoids a potentially life-threatening skin reaction in 3% of patients.¹⁸ In cardiovascular medicine, initial results of clinical trials suggest either no effect or a modest effect of genotyping to keep anticoagulation therapeutic during warfarin therapy.

A difficulty with such drug-specific approaches is that the benefit of the genotype data must be large to justify the cumbersomeness and cost of testing all exposed subjects. Although the probability is small that genetic variation plays an important role in predicting the response of an individual patient to a specific drug, it is likely that when many drugs are prescribed for a population of patients, each patient will display genetically determined aberrant responses to some drugs. This reasoning underlies the concept of preemptive genotyping, in which many genetic variants relevant to many variable drug responses are assayed in subjects who have not yet been exposed to the drugs.¹⁹ These data are then stored in EMR systems with advanced point-of-care decision support capabilities that deliver instantaneous advice when a drug is prescribed to a patient with known genomic variants.²⁰ Several technological developments enable this vision, and these include advanced EMRs and multiplexed inexpensive genotyping assays that interrogate many

polymorphisms for the same cost as a handful relevant to one drug. The concept is now being tested at a handful of medical centers with the goal of testing the idea, establishing its cost and benefit, and optimizing this approach to implementing pharmacogenomic information into health care.

FUTURE CHALLENGES

The past 25 years have seen dramatic advances in the treatment of heart disease, in no small part because of the development of highly effective and well-tolerated drug therapies such as with HMG-CoA reductase inhibitors, ACE inhibitors, and beta blockers. These developments, along with improved nonpharmacologic approaches, have led to dramatically enhanced survival of patients with advanced heart disease. Thus, polypharmacy in an aging and chronically ill population is becoming increasingly common. In this milieu, drug effects become increasingly variable, reflecting interactions among drugs, underlying disease and disease mechanisms, and genetic backgrounds. Furthermore, despite advances in the Western world, cardiovascular disease is emerging as an increasing problem worldwide as infectious diseases, formerly predominant contributors to morbidity and mortality, are coming under control and smoking continues to increase. Understanding the way in which genetic background plays into disease susceptibility and responses to drug therapy, concepts largely tested in only white populations to date, represents a major challenge in cardiovascular medicine.

More generally, an important point is that genomic science is still in its infancy, so reported associations require independent confirmation and assessment of clinical importance and cost-effectiveness before they can or should enter clinical practice. Importantly, most pharmacogenomic studies reported to date have focused on common variants with relatively large effects on phenotypes like drug concentrations or drug responses. However, application of modern sequencing technologies has revealed that the vast majority of polymorphisms are uncommon (minor allele frequencies under 1%), and *CYP* and other genes relevant to pharmacogenomics are no exception. Developing approaches to establish the clinical impact of such rare variants on drug responses is an emerging challenge.

This challenge is all the more acute because the cost of sequencing has fallen drastically since the completion of the first-draft human genome in 2000, and the sub-\$1000 whole-genome sequence is likely to be a reality in 2014. This may be enabling for the preemptive pharmacogenomic strategy just outlined, as well as a broader vision of

genome-guided healthcare but presents major challenges in data storage and mining.

The relationship between the prescriber and the patient remains the centerpiece of modern therapeutics. An increasingly sophisticated molecular and genetic view of response to drug therapy should not change this view, but rather complement it. Each initiation of drug therapy represents a new clinical experiment. Prescribers must always be vigilant regarding the possibility of unusual drug effects, which could provide clues about unanticipated and important mechanisms of beneficial and adverse drug effects.

REFERENCES, 92

We use biomarkers daily in the practice of cardiovascular medicine. Moreover, the use of biomarkers has the potential to continue to improve our ability to provide clinically effective and cost-effective cardiovascular medicine in the years to come. Appropriate risk stratification and targeting of therapies should not only help improve patient outcomes but also assist in responding to the urgent need to “bend the cost curve” of medical care. In particular, excessive use of imaging biomarkers increases the cost of medical care and can jeopardize patient outcomes (for example, radiation exposure or complications of administering contrast material or investigating incidental findings). Inappropriate use or interpretation of blood biomarkers (e.g., cardiac troponin levels) can lead to unnecessary hospitalization or procedures as well.

Despite the current usefulness of biomarkers, their future promise, and the critical need to use them appropriately, a great deal of misunderstanding surrounds their current clinical application. In addition, contemporary technologies have the potential to greatly expand the gamut of biomarkers relevant to cardiovascular practice. Emerging genetic, proteomic, metabolomic, and molecular imaging strategies will surely transform the landscape of cardiovascular biomarkers (see also Chapters 7, 8, 9, and 42). This chapter provides a primer on cardiovascular biomarkers by defining some terms and discussing how the application of biomarkers can assist in clinical care, in addition to exploring some emerging technologies. Finally, we discuss an approach to the rigorous evaluation of the clinical usefulness of biomarkers. Advances in cardiovascular biology and the application of novel technologies have identified a plethora of novel cardiovascular biomarkers of potential clinical usefulness—begging the question of whether a novel biomarker adds value to existing and often better-validated biomarkers. Thus clinicians need tools to evaluate these emerging biomarkers, adoption of which may elevate clinical practice and improve patient outcomes.

WHAT IS A BIOMARKER?

For regulatory purposes, the U.S. Food and Drug Administration (FDA) first defined a *biomarker* in 1992 as “a laboratory measure or physical sign that is used in therapeutic trials as a substitute for a clinically meaningful end point that is a direct measure of how a patient feels, functions, or survives and is expected to predict the effect of the therapy.” At that time the FDA considered a *surrogate endpoint* as “reasonably likely, based on epidemiologic, therapeutic, pathophysiologic, or other evidence to predict clinical benefit.”¹ The National Institutes of Health (NIH) convened a working group in 1998

that offered some parallel operating definitions to guide the biomarker field (Table 10-1).² They defined a biologic marker—biomarker for short—as “a characteristic that is objectively measured and evaluated as an indicator of normal biologic processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention.” Thus the NIH definition embraces not only soluble biomarkers in circulating blood but also “bedside biomarkers” such as anthropomorphic variables obtainable with a blood pressure cuff or a tape measure at the point of care. This broad definition encompasses not only measurements of biomarkers in blood (Fig. 10-1A) but also those derived from a variety of techniques, including measurements from imaging studies (Fig. 10-1B). Imaging biomarkers can include those derived from classic anatomic approaches. Imaging modalities now offer functional information, such as estimates of ventricular function, myocardial perfusion, and the like. Molecular imaging has the potential to target specific molecular processes. A functional classification of biomarkers helps sort through the plethora encountered by the clinician inasmuch as biomarkers can reflect a variety of biologic processes or organs of origin. For example, as a first approximation, cardiac troponin reflects myocardial injury, brain natriuretic peptide reflects cardiac chamber stretch, C-reactive protein (CRP) reflects inflammation, and the estimated glomerular filtration rate reflects kidney function (see Fig. 10-1B).

The NIH working group also provided further definitions relevant to the field of biomarkers. They defined a “surrogate endpoint” as “a biomarker intended to substitute for a clinical endpoint. A surrogate endpoint is expected to predict clinical benefit (or harm), or lack of benefit (or harm) based on epidemiologic, therapeutic, pathophysiologic, or other scientific evidence.” (Note that the NIH definitions do not include the commonly used term “surrogate marker.”) (Table 10-1). Thus a surrogate endpoint is a biomarker that has been “elevated” to surrogate status. This distinction has particular importance in the regulatory aspects of cardiovascular medicine. For example, the FDA previously accepted a certain degree of reduction in hemoglobin A1c (HbA1c) as a criterion for registration of a novel oral hypoglycemic agent—thus HbA1c was considered a biomarker accepted as a surrogate endpoint. Current FDA guidance now requires a cardiovascular safety study for the registration of new medications that target diabetes.³ This policy indicates doubts about the fidelity of a drop in HbA1c as a surrogate endpoint for reduced cardiovascular risk in the eyes of regulatory authorities despite its value as a biomarker of glycemia.

The NIH working group defined a “clinical endpoint” as “a characteristic or variable that reflects how a patient feels, functions, or survives” (Table 10-1). Pivotal or phase III cardiovascular trials aspire

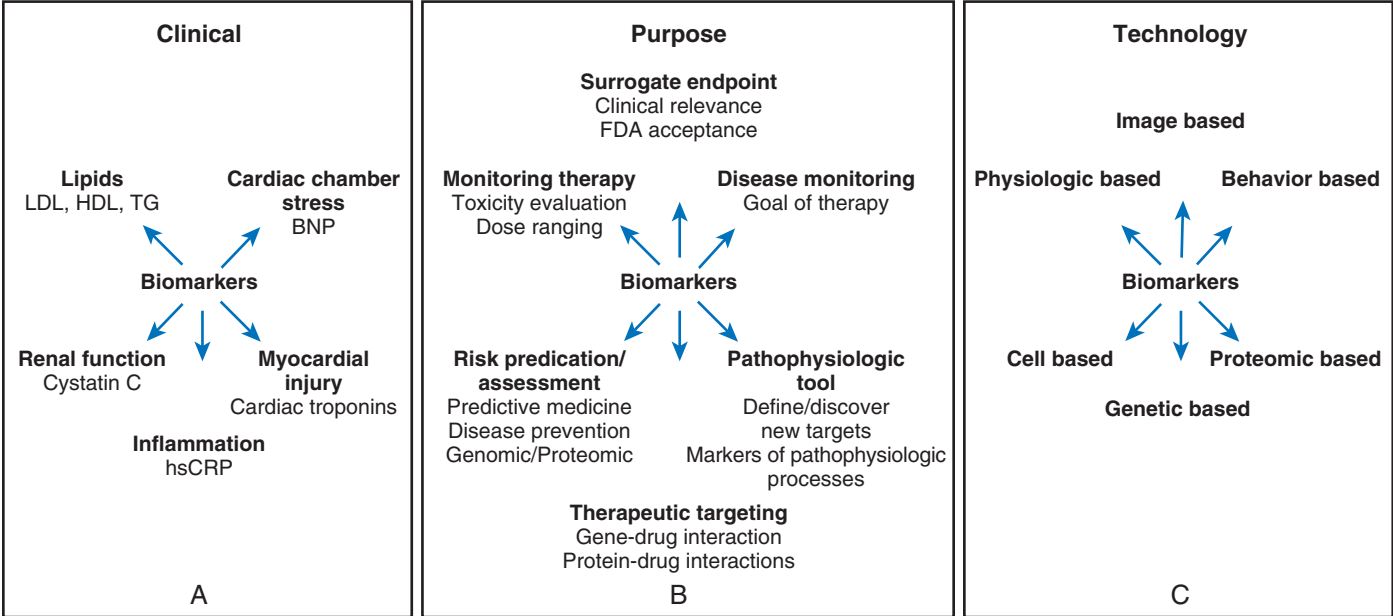

FIGURE 10-1 Examples of commonly used clinical biomarkers for cardiovascular disease (A), as well as research-oriented biomarkers categorized according to purpose (B) and technology (C). BNP = brain natriuretic peptide; TG = triglyceride.

TABLE 10-1 National Institutes of Health Biomarkers Definition Working Group (1998)

Biologic Marker (Biomarker)
A characteristic that is objectively measured and evaluated as an indicator of normal biologic processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention.
Surrogate Endpoint
A biomarker intended to substitute for a clinical endpoint. A surrogate endpoint is expected to predict clinical benefit (or harm or lack of benefit or harm) based on epidemiologic, therapeutic, pathophysiologic, or other scientific evidence.
Clinical endpoint
A characteristic or variable that reflects how a patient feels, functions, or survives.

to use clinical endpoints as defined above. The distinction between biomarkers, surrogate endpoints, and clinical endpoints has crucial implications as practitioners, regulators, and payers increasingly demand evidence of improvements in actual clinical outcomes rather than mere manipulation of biomarkers as a criterion for adoption of a treatment in clinical practice.

Clinical Applications of Cardiovascular Biomarkers

Much of the prevailing confusion regarding biomarkers involves framing the question that one wants to answer with the use of a biomarker (Fig. 10-1C). We can classify the goals of application of cardiovascular biomarkers into several rubrics.

1. **Diagnosis:** The use of biomarkers for cardiovascular diagnosis has daily familiarity to practitioners of cardiovascular medicine. The current universal definition of myocardial infarction, for example, requires elevation of a biomarker of myocyte injury, such as cardiac-specific isoforms of troponin.
2. **Risk stratification:** Familiar examples of biomarkers used in risk stratification in cardiovascular medicine include systolic blood pressure or low-density lipoprotein (LDL) cholesterol. These

biomarkers reliably predict future risk for cardiovascular events on a population basis.

3. **Goals for therapy:** Our contemporary guidelines often specify cut points for targets of treatment—for example, a specific level of a biomarker such as systolic blood pressure or LDL cholesterol in a particular group of individuals. Practitioners of cardiovascular medicine commonly use the biomarker international normalized ratio (INR) to titrate the dosage of warfarin administered to an individual patient. Abundant data support the clinical benefit of maintaining the INR within a certain range in various patient groups—an example of a widely used biomarker that has proven clinical usefulness as a goal for therapy.
4. **Targeting of therapy:** In clinical practice, using biomarkers to target therapy has great usefulness and promise as we move toward a more comprehensive “personalized medicine” approach to practice (see Chapter 8). Examples of biomarkers used to target therapy include troponin measurements to triage patients with acute coronary syndromes for early invasive management or measurement of high-sensitivity C-reactive protein (hsCRP) to allocate statin treatment to individuals with below-average LDL cholesterol.
5. **Drug development, evaluation, and registration:** Biomarkers have critical importance in the development of new pharmacologic agents. Biomarkers can provide early signals of efficacy that will help prioritize agents more likely to provide benefit on clinical endpoints in large-scale trials. Inappropriate dose selection represents a major mode of failure of clinical trials. Judicious use of biomarkers can help in selecting an appropriate dose of an agent to study in a large endpoint trial. Finally, biomarkers accepted as surrogate endpoints prove useful to regulatory agencies in granting approval for novel therapies.

Clinical use of cardiovascular biomarkers requires a clear understanding of *how* they should be used. Many biomarkers provide clinically useful information when measured once at “baseline.” A baseline measurement of high-density lipoprotein (HDL) cholesterol, for example, indubitably correlates inversely with future risk for cardiovascular events. Yet serial measurement of biomarkers to document a change does not always guarantee a clinical benefit. In the case of HDL, recent large-scale trials that have measured clinical endpoints have cast doubt on the fidelity of a rise in HDL cholesterol as a predictor of clinical benefit (see Chapter 45).

Biomarkers require rigorous validation before adoption into clinical practice. In cardiovascular medicine, LDL cholesterol has high reliability as a biomarker; it satisfies the modified Koch postulates. LDL levels prospectively predict cardiovascular risk, and drops in LDL generally correlate with improved outcomes. Not all biomarkers, though, have proved as faithful in predicting clinical events. In the 1960s and 1970s, for example, most of the cardiovascular community considered ventricular premature depolarizations on the electrocardiogram as important biomarkers for lethal arrhythmias. Numerous strategies have been aimed at suppressing ventricular ectopy. CAST (Cardiac Arrhythmia Suppression Trial), however, showed that drugs capable of suppressing ventricular premature depolarizations actually worsened clinical endpoints. The short-term improvements in indices of cardiac contractility produced by inotropic agents similarly led to worsened clinical outcomes, including increased mortality. These examples illustrate the necessity of rigorous validation of biomarkers before adoption into clinical practice.

Another important consideration in the use of cardiovascular biomarkers involves the question of causality. LDL cholesterol exemplifies a causal biomarker, one that clearly participates in the pathogenesis of atherosclerosis. Its levels prospectively correlate with risk for cardiovascular events and the development of atherosclerotic lesions identified by a variety of imaging modalities. A variety of independent manipulations of LDL levels correlate with clinical outcomes. Finally, very strong genetic evidence based on mendelian disorders (e.g., familial hypercholesterolemia) and unbiased genome-wide association scans, as well as mendelian randomization analyses, has established LDL cholesterol as a causal risk factor in atherosclerotic cardiovascular disease and as a generally valid surrogate endpoint offering great value in clinical practice (see Chapter 45).^{4,5} For a biomarker that has a causal role, the expected random population distribution of a polymorphism that determines high or low biomarker concentrations would be skewed in individuals, depending on their disease status.

Other biomarkers, although clearly clinically useful, do not participate in the causal pathway for disease. For example, fever has served since antiquity as an important biomarker of infection. Resolution of fever correlates with successful resolution of infectious processes. Yet fever does not participate causally in the pathogenesis of infection but merely serves as a biomarker of the host defenses against the infectious process. Similarly, the use of hsCRP measurements improves the prediction of cardiovascular risk, and reductions in CRP correlate with clinical benefit in many cases. Yet, evidence supporting a causal role for CRP in the pathogenesis of cardiovascular disease lacks strength.⁶

These examples illustrate how a biomarker does not have to reside in the causal pathway of a disease to have clinical usefulness. A clear and early exposition of the uses and pitfalls in the application of biomarkers emerged from the landmark work of Fleming and DeMets (Fig. 10-2).⁷ Biomarkers have the greatest potential for validity when there is one causal pathway and when the effect of intervention on true clinical outcomes is mediated directly through the biomarker surrogate (Fig. 10-2A). But, biomarker development can fail when the biomarker turns out not to be in the causal pathway, when the biomarker is insensitive to the specific intervention's effect, or when the intervention of interest has a mechanism of action (or a toxicity) that is independent of the pathway described by the biomarker (Fig. 10-2B-E). These examples do not mean that biomarkers lack value. Quite the contrary, few—if any—novel biologic fields could develop without biomarker discovery and validation. Yet surrogate endpoints probably will not replace large-scale randomized trials that address whether interventions reduce actual event rates.

Novel Technologies in the Identification of Biomarkers

The limitations of currently available biomarkers for screening or prognostic use underscore the importance of identifying “uncorrelated” or “orthogonal” biomarkers associated with novel disease pathways. Most current biomarkers have been developed as

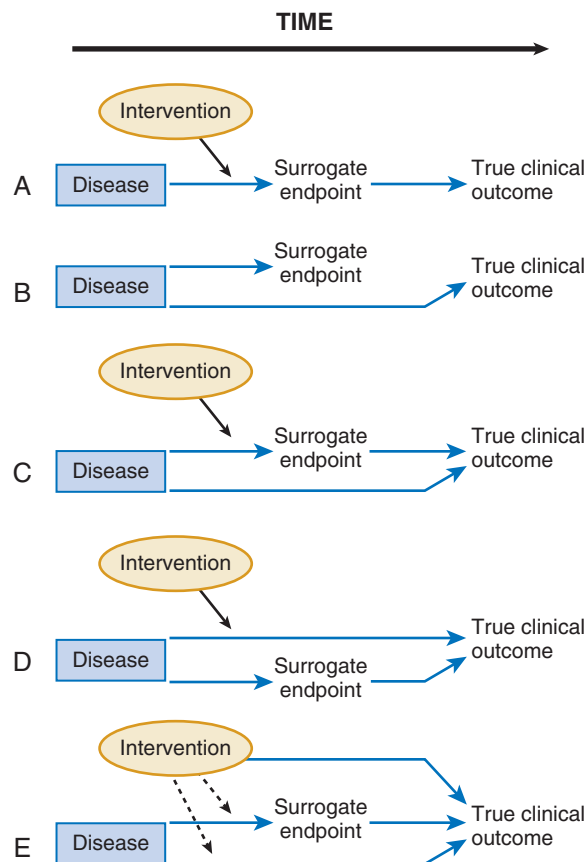

FIGURE 10-2 Biomarkers as surrogate endpoints in clinical research. **A**, The setting that provides the greatest potential for the surrogate endpoint to be valid. **B**, The surrogate is not in the causal pathway of the disease process. **C**, Of several causal pathways of disease, the intervention affects only the pathway mediated through the surrogate. **D**, The surrogate is not in the pathway of the intervention's effect or is insensitive to its effect. **E**, The intervention has mechanisms of action independent of the disease process. Dotted lines represent possible mechanisms of action. (Modified from Fleming TR, DeMets DL: *Surrogate end points in clinical trials: Are we being misled?* Ann Intern Med 125:605, 1996.)

an extension of targeted physiologic studies investigating known pathways such as tissue injury, inflammation, or hemostasis. By contrast, emerging technologies now enable the systematic, unbiased characterization of variation in proteins and metabolites associated with disease conditions.

INTRODUCTION TO PROTEOMICS AND METABOLOMICS

Of the emerging platforms for biomarker discovery, perhaps none have garnered more recent attention than proteomics and metabolomics. Proteomics aims to catalogue the entire protein products of the human genome. By contrast, metabolomics attempts to systemically capture smaller biochemical compounds, including simple amino acids and related amines, as well as lipids, sugars, nucleotides, and other intermediary metabolites. Although still in their infancy with respect to other approaches, proteomics and metabolomics offer insight into the full complexity of a given disease phenotype (Fig. 10-3). Because proteins and metabolites are downstream of genetic variation and transcriptional changes, they provide instantaneous “snapshots” of the state of a cell or organism. They can rapidly change in response to environmental stressors such as exercise or directly by the ingestion of foods or other compounds. A growing body of literature suggests unanticipated roles of small proteins and metabolites in the control of biologic functions such as blood pressure and energy homeostasis.^{8,9} Thus metabolomics and proteomics may not

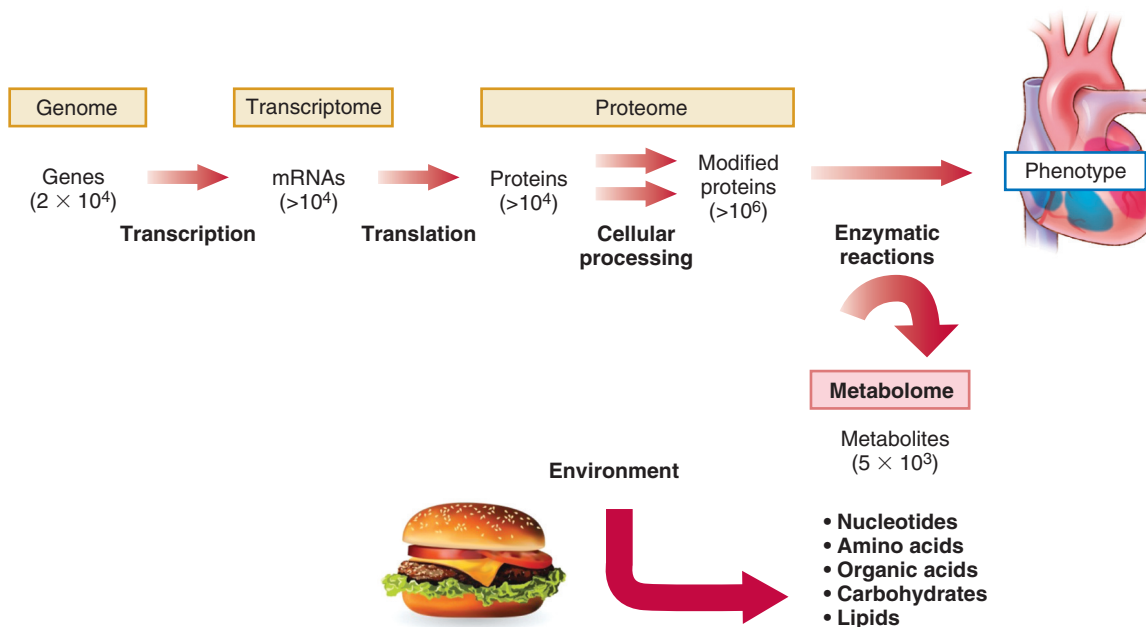

FIGURE 10-3 The conceptual relationship of the genome, transcriptome, proteome, and metabolome. Informational complexity increases from genome to transcriptome to proteome. The estimated number of entities of each type of molecule in humans is indicated in parentheses.

only identify novel biomarkers but also provide information on biology and highlight potential therapeutic targets.

The term *proteome* was coined in the 1990s with the increasing realization that although all cells of a given organism contain an equivalent genomic content, their protein content does not represent all possible proteins that the genome can express. Selective gene expression during development and differentiation and in response to external stimuli results in each cell expressing only a subset of the encoded proteins at any given time. One can speak not only of the general human proteome but also more specifically about the proteome of tissues such as the heart, of specific cells such as cardiac myocytes, and even of subproteomes that correspond to particular organelles or biologic compartments, such as mitochondria.

The proteome provides information beyond the messenger RNA (mRNA) expression profile of a particular genome. Studies suggest that gene expression often correlates poorly with protein levels.¹⁰ Protein expression depends not only on transcription but also on mRNA stability and rates of protein synthesis and degradation, so the presence or absence of mRNA may not accurately reflect levels of the corresponding protein. Following transcription and translation, proteins may undergo one or more of dozens of potential post-translational modifications (such as phosphorylation, glycosylation, acetylation, or sulfation) at multiple sites. Subsequent enzymatic and nonenzymatic alterations greatly expand the number of simultaneously existing protein species.

When compared with proteomics techniques, metabolomics technologies focus on smaller compounds, generally less than 2 kDa in size. Metabolites are usually easily separated from protein constituents by simple extraction techniques and precipitation and removal of the proteins. As early as the 1970s, Arthur Robinson and Linus Pauling postulated that the quantitative and qualitative pattern of metabolites in biologic fluids reflected the functional status of the complex biologic system from which they were derived.¹¹ The term “metabolic profiling” was introduced to describe data obtained from gas chromatographic analysis of a patient sample.¹² This emerging approach to quantitative metabolic profiling of large numbers of small molecules in biofluids was ultimately termed “metabonomics” by Nicholson and colleagues¹³ and “metabolomics” by others. Recently, more focused analyses of specific metabolite families or subsets have given rise to new terms such as “lipidomics.” In terms of applications to human diagnostics, seminal studies of inborn

errors of metabolism in infants have served as a key springboard. Millington and colleagues pioneered the use of mass spectrometry (MS)-based methods for monitoring fatty acid oxidation, as well as organic and selected amino acids. Their work has culminated in neonatal screening for metabolic disorders,¹⁴ thereby enabling the identification of infants with fatty acid oxidation disorders, organic acidemias, and aminoacidopathies. In certain situations, rapid identification of these disorders triggers intervention in the form of dietary modulation, with beneficial therapeutic effects. A global metabolomic or proteomic analysis of more common complex diseases might similarly spotlight pathways for dietary or drug modulation.

Analytic Challenges for Proteomics and Metabolomics

The many classes of proteins and chemicals present analytic challenges, particularly as applied to searching for biomarkers in blood. Many different types of cells contribute to the plasma proteome and metabolome, thus increasing their complexities and presenting challenges to interpretation of the data that emerge. In the case of the proteome, the 22 most abundant proteins, including albumin and the immunoglobulins, account for 99% of the total proteome mass (Fig. 10-4). Many of the biologically interesting molecules relevant to human disease occur in low abundance. Cardiac markers such as troponin circulate in the nanomolar range, insulin in the picomolar range, and tumor necrosis factor in the femtomolar range. Plasma contains tens of thousands of unique protein species in concentrations spanning a range of more than 10 orders of magnitude. Indeed, some suggest that the plasma proteome might encompass the entire set of human polypeptide species resulting from splice variants and post-translational modifications¹⁵ because the protein content of plasma unexpectedly includes proteins of all functional classes and from apparently all cellular localizations. Most low-abundance proteins in plasma are intracellular or membrane proteins that are present in plasma as a result of cellular turnover.¹⁶ By contrast, recent estimates suggest that the human metabolome may include approximately 5000 small molecules¹⁷ and thus may be somewhat more tractable to analyze and systematize than the human proteome.

Several features contribute critically to the success of proteomic or metabolomic technologies. First, the technique must have the

FIGURE 10-4 Reference concentration for representative protein analytes in plasma. Protein abundance is plotted on a log scale spanning 12 orders of magnitude. When only an upper limit is quoted, the lower end of the interval line shows an arrowhead. The classic plasma proteins are clustered to the left (high abundance), the tissue leakage markers (e.g., enzymes and troponins) are clustered in the center, and the cytokines are clustered to the right (low abundance). TPA = tissue plasminogen activator; G-CSF = granulocyte colony-stimulating factor; MIP = macrophage inflammatory protein; RANTES = regulated on activation, T cell expressed and secreted; TNF = tumor necrosis factor; TPA = tissue plasminogen activator. (From Anderson NL, Anderson NG: *The human plasma proteome: History, character, and diagnostic prospects*. *Mol Cell Proteomics* 2:50, 2003.)

capability of identifying a wide breadth of proteins or metabolite analytes within complex biologic samples across a broad range of physical characteristics, including size and charge. Second, the technologies must be sensitive enough to probe the proteome or metabolome to adequate “depths”—that is, to provide resolution of

biologically active compounds of the lowest abundance. Frequently, the least abundant entities play critical regulatory roles in the response to physiologic stressors. Third, tools must also work across a broad dynamic range, a notion underscored in Figure 10-4—they must be able to simultaneously identify both more abundant and less abundant proteins in the same complex mixture. Unfortunately, most analytic techniques apply well only across concentrations of several orders of magnitude. Finally, the ideal technology should be stable and reproducible, an attribute necessary for minimizing artifacts during initial discovery, validation, and testing for clinical applications.

Robust, searchable databases for validation of identified proteins or metabolites represent an increasingly crucial support for biomarker discovery. The scope of investigation addressable by these techniques has widened immeasurably since completion of the Human Genome Project. At present, the human databases are the largest and easiest to use, which will help accelerate translational investigation. Genomic databases collectively provide a catalog of all known or theoretical proteins expressed in organisms for which databases exist. Software that can search through databases for identification of candidates has proved essential to interpretation of the data; much of this software is available on the Internet. Collaborative efforts have recently begun to catalog both the human proteome and the plasma metabolome.

OVERVIEW OF THE DISCOVERY PROCESS

Figure 10-5 summarizes the essential elements of the discovery approach by using a proteomics experiment as an example. Biologic samples consist of a complex mixture containing intact and partially degraded proteins and metabolites of various molecular weights, modifications, and solubility. The chance of identifying proteins or metabolites in a mixture increases as the complexity of the mixture decreases. As suggested by Liebler,¹⁸ the problem of complexity and how to deal with it resembles the process of printing a book. Printing all the words on a single page could be accomplished quickly, but the resulting page would be illegibly black with ink; dividing the text into multiple pages reduces the complexity to reveal organized text. Samples can be analogously enriched for certain components through fractionation or affinity depletion columns, but all preparative procedures—including solubilization, denaturation, and reduction processes—should be compatible with the constraints of subsequent analysis steps. The quest to reduce complexity requires careful balance against the possibility that each additional step might also introduce undesired protein or metabolite modifications or loss.

Several analytic techniques can serve to identify metabolites or proteins, although MS instrumentation offers an unrivaled ability to provide several layers of complementary information, which has benefited tremendously from whole-genome analysis and the genomics revolution. MS provides accurate mass detection of peptides from proteolytic digests of complex protein mixtures or small metabolites derived from tissues or blood. The set of peptide or metabolite mass measurements can be searched in databases to obtain definitive identification of the parent proteins or metabolites of interest. Favorably compared against other proteomics and metabolomics technologies, MS offers high sensitivity and amenability to automation, thus promoting high-throughput processing. MS has a wide range of applicability and not only detects metabolites and proteins but also characterizes any post-translational modifications.

Mass spectrometers are composed of modular elements, including an ion source, mass analyzer, and a detector/recorder (Fig. 10-6). MS instruments are classified according to the ionization source and mass analyzer used, but all process samples as gas-phase ions, the movements of which are precisely measured within an electromagnetic field. An ion source generates these gas-phase ions from the analyte through a variety of available techniques, from either the solid state by matrix-assisted laser desorption/ionization (MALDI) or directly from the liquid phase by electrospray ionization (ESI). A coupled chromatographic separation step fractionates complex sample mixtures before ESI spectroscopic analysis. The gas-phase ions then enter the mass analyzer, which resolves the peptides based on their mass-to-charge (m/z) ratio. Examples of commonly used mass analyzers include the

quadrupole mass filter, ion trap mass analyzer, and time-of-flight mass analyzer. Finally, the detector records the ions via an electronic multiplier and records ion intensity versus the m/z value to create the resulting MS spectra.

These technologies can be used to characterize biologic fluids either in a targeted manner or in a pattern discovery manner. In the former, the investigator targets a predefined set of analytes to be quantitated. For example, libraries of metabolites can be purchased and their chromatographic and MS characteristics determined empirically by “spiking” reference standards into plasma. Endogenous metabolites can then be quantified based on the information ascertained from the known standards. The targeted approach now readily permits assay of several hundred metabolites in as little as tens of microliters of plasma. In the pattern discovery experiment, by contrast, the investigator confronts a complex pattern of peaks, many of which are anonymous—the molecular identities of the species that give rise to the peaks are not generally known. Although the targeted approach is more limiting, the analysis is more straightforward because the analytes yielding the signals are already known. The untargeted or “fingerprint” approach has less inherent bias, but unambiguous identification of the peaks can prove laborious and difficult. In clinical samples, considerable care must be taken to rule out spurious associations—for example, confounding related to drug treatment.

Applications of Mass Spectrometry-Based Discovery to Cardiometabolic Disease

In an initial proof-of-principle study using a targeted metabolite profiling approach, Newgard and colleagues profiled obese versus lean humans to gain a broad understanding of the metabolic and physiologic differences in these two disparate groups.¹⁹ Their studies identified a branched-chain amino acid signature that correlated highly with the metrics of insulin resistance. Complementary studies in two large population-based cohorts demonstrated that branched-chain and aromatic amino acid concentrations associate significantly with incident type 2 diabetes up to 12 years before the onset of overt disease.²⁰ Adjustment for established clinical risk factors did not substantially attenuate the strength of these associations. Furthermore, the branched-chain amino acid signature also predicts atherosclerosis even after adjusting for the metrics of insulin resistance and diabetes.²¹ For those in the top quartile of branched-chain amino acid levels, the odds for development of cardiometabolic disease exceeded any single-nucleotide polymorphism identified to date. Taken together, these findings have disclosed dysregulation of amino acid metabolism very early in the development of cardiometabolic diseases. Ongoing studies are examining the relative genetic versus environmental contributions to these findings.

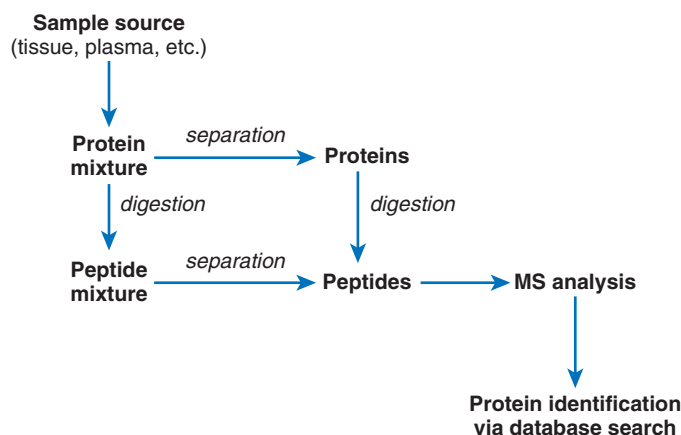

FIGURE 10-5 Overview of a proteomics experiment.

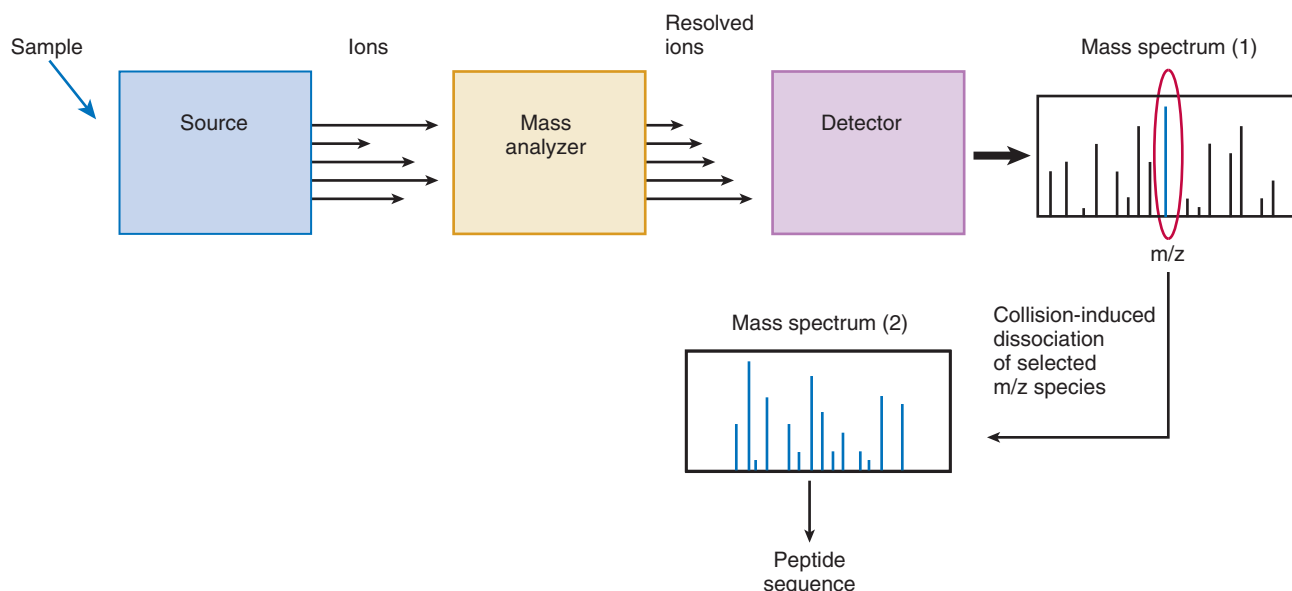

FIGURE 10-6 Schematic of tandem MS. m/z = mass-to-charge ratio.

In a translational study using nontargeted liquid chromatography–MS–based metabolite profiling applied to cardiovascular disease, Wang and associates first profiled the plasma of 75 individuals from a hospital-based cohort who experienced a myocardial infarction, stroke, or death in the ensuing 3 years and 75 age- and sex-matched controls who did not.²⁰ Of 18 analytes that differed significantly between cases and controls, 3 demonstrated significant correlations among one another, thus suggesting a potential common biochemical pathway. Using complementary analytic methods, these metabolites were identified as betaine, choline, and trimethylamine-*N*-oxide, all metabolites of dietary phosphatidylcholine. Dietary supplementation of choline was sufficient to promote atherosclerosis in mice, and suppression of the intestinal bacteria responsible for the conversion of phosphatidylcholine to choline inhibited this atherogenesis. In addition to reinforcing the interaction between diet, gut bacteria, and the metabolome, this study demonstrated how metabolomic biomarker discovery can elucidate novel pathways to disease.

Future Directions in Biomarker Discovery

Identification of new biomarkers for cardiovascular disease depends on the complementary power of genetics, transcriptional profiling, proteomics, and metabolomics. As discussed in the next section, the clinical usefulness of new biomarkers will require rigorous evaluation of their ability to improve the prediction of risk or to direct and monitor management in an individual, the ultimate goal of personalized medicine. In addition to risk biomarkers, diagnostic biomarkers could help in making challenging acute diagnoses such as reversible myocardial ischemia, pulmonary embolism, and aortic dissection. The evolution of a clinical biomarker requires a long journey and an arduous transition from the research environment to clinical practice. Emerging technologies such as those described above have the potential to permit systematic assessment of variation in genes, RNA, proteins, and metabolites for identification of “uncorrelated” or “orthogonal” biomarkers that probably would not emerge with a focus on candidates from well-studied pathways.

CLINICAL MEASURES OF BIOMARKER PERFORMANCE

When considering any biomarker in a clinical setting for risk prediction, physicians should ask two interrelated questions. First, is there clear evidence that the biomarker of interest predicts future cardiovascular events independent of other already measured biomarkers? Second, is there clear evidence that those identified by the biomarker of interest will benefit from a therapy that they otherwise would not have received?²² If the answer to both these questions is not a clear “yes,” an argument can be made that measuring the biomarker will not probably have sufficient usefulness to justify its cost or unintended consequences. Such judgments require clinical expertise and will vary on a case-by-case basis.

Biomarker evaluation also typically involves repeated testing in multiple settings that include varied patient populations and that use different epidemiologic designs. Prospective cohort studies (in which the biomarker or exposure of interest is measured at baseline, when individuals are healthy, and then related to the future development of disease) provide a much stronger form of epidemiologic evidence than do data from retrospective case-control studies (in which the biomarker of interest is measured after the disease is present in the case subjects).

After discovery by the technologies described above or identification by a candidate approach, a novel biomarker typically requires development in a translational laboratory for refinement of its assay to address issues of interassay and intra-assay variation before any clinical testing begins. Focused studies in specific patient populations typically follow and eventually broaden to encompass the population of greatest clinical interest. Beyond simple reproducibility, biomarkers under development for diagnostic, screening, or predictive purposes require further evaluation with a standard set of

TABLE 10-2 Summarizing the Results of Screening, Diagnostic, or Predictive Tests

	DISEASE PRESENT	DISEASE ABSENT	
Test positive	a	b	a + b
Test negative	c	d	c + d
Total	a + c	b + d	
Sensitivity = $a/(a + c)$			
Specificity = $d/(b + d)$			
Positive predictive value = $a/(a + b)$			
Negative predictive value = $d/(c + d)$			

a = number of individuals for whom the screening test is positive and the individual actually has the disease (true positives); b = number of individuals for whom the test is positive but the individual does not have the disease (false positives); c = number of individuals for whom the test is negative but the individual actually has the disease (false negatives); d = number of individuals for whom the test is negative and the individual does not have the disease (true negatives).

performance measures that include sensitivity, specificity, positive and negative predictive value, discrimination, calibration, reclassification, and tests for external validity. These terms and their use in clinical biomarker development are outlined below.

Sensitivity, Specificity, and Positive and Negative Predictive Value

The validity of a screening or diagnostic test (or one used for prediction) is initially measured by its ability to correctly categorize individuals who have preclinical disease as “test positive” and those without preclinical disease as “test negative.”²³ A simple two-by-two table is commonly used to summarize the results of a screening test by dividing those screened into four distinct groups (Table 10-2). In this context, sensitivity and specificity provide fundamental measures of the test’s clinical validity. Sensitivity is the probability of testing positive when the disease is truly present and is defined mathematically as $a/(a + c)$; as sensitivity increases, the number of individuals with disease who are missed by the test decreases, so a test with perfect sensitivity will detect all individuals with disease correctly. In practice, tests with ever-higher sensitivity tend to also classify as “diseased” many individuals who are not actually affected (false positives). Thus the specificity of a test is the probability of screening negative if the disease is truly absent and is defined mathematically as $d/(b + d)$. A test with high specificity will rarely be positive when disease is absent and will therefore lead to a lower proportion of individuals without disease being incorrectly classified as test positive (false positives). A simple way to remember these differences is that sensitivity is “positive in disease” whereas specificity is “negative in health.”

A perfect test has both very high sensitivity and specificity and thus low false-positive and false-negative classifications. Such test characteristics are rare, however, because there is a tradeoff between sensitivity and specificity for almost every screening biomarker, diagnostic, or predictive test in common clinical use. For example, although high LDL cholesterol levels commonly serve as a biomarker for atherosclerotic risk, up to half of all incident cardiovascular events occur in those with LDL cholesterol levels well within the normal range, and many events occur even when LDL cholesterol levels are low. If the diagnostic cutoff criterion for LDL cholesterol is reduced so that more people who actually have high risk for disease will be test positive (i.e., increase sensitivity), an immediate consequence of this change will be an increase in the number of people without disease in whom the diagnosis is made incorrectly (i.e., reduced specificity). Conversely, if the criterion for diagnosis or prediction is made more stringent, a greater proportion of those who test negative will actually not have the disease (i.e., improved specificity), but a larger proportion of true cases will be missed (i.e., reduced sensitivity).

In addition to sensitivity and specificity, the performance or yield of a screening, diagnostic, or predictive test also varies depending on the characteristics of the population being evaluated. Positive and negative predictive values are terms used in epidemiology that refer to measurement of whether an individual actually has (or does not have) a disease, contingent on the result of the screening test itself.

The positive predictive value (PPV) is the probability that a person has the disease of interest, given that the individual tests positive, and is mathematically calculated as $PPV = a/(a + b)$. High PPV can be anticipated when the disease is common in the population being tested. Conversely, the negative predictive value (NPV) is the probability that an individual is truly disease free, provided that the test has a negative result, and is mathematically calculated as $NPV = d/(c + d)$. High NPV can be anticipated when the disease is rare in the population being tested. Although sensitivity and specificity are largely performance characteristics of the test itself (and thus tend to be fixed values), PPV and NPV depend in part on the population being tested (and thus tend to vary).²³

Discrimination, C-Statistics, and the Receiver Operative Characteristic Curve

Discrimination is the ability of a test (or prognostic model) to separate those with disease or at high risk for disease (cases) from those without disease or at low risk for disease (controls). The most common method used to measure discrimination has been the area under the receiver operating characteristic (ROC) curve, which relates sensitivity (on the y axis) to (1 – specificity) (on the x axis) across a full range of cutoff values for the test or screening algorithm of interest (Fig. 10-7).

Given a population of individuals being evaluated, the area under the ROC curve—also called the C-statistic—equals the probability of correctly ranking risk for individuals by using the test or model under evaluation. A random test with no clinical usefulness would have a C-statistic (or area under the ROC curve) of 0.5, which corresponds to the diagonal line in Figure 10-7. A perfect test that completely discriminates individuals with disease from those without disease would have a C-statistic that approaches 1.0. As the C-statistic increases from 0.5 to 1.0, model fit (or test accuracy) improves—thus the change in the C-statistic has been used historically to judge whether a new biomarker can “add” significantly to those already in

FIGURE 10-7 ROC curves for a series of biomarkers or risk prediction models with incremental improvement. The diagonal line corresponds to a random effect (C-statistic = 0.5), whereas the increasing C-statistic corresponds to improving model discrimination.

use. This approach permits direct comparison of the relative efficiency of multimarker panels. For example, using comparative C-statistic analyses, investigators in the Emerging Risk Factors Collaboration recently found that the incremental clinical usefulness of CRP has similar magnitude as that of total and HDL cholesterol.²⁴ Thus when change in the C-statistic can be demonstrated and the overall power to do so is adequate, this test can aid understanding of the impact that novel pathways and novel risk biomarkers have on prediction and prevention.

Unfortunately, as Cook has shown in several settings,^{25,26} the traditional C-statistic approach is limited in that biomarkers with large associations may have little effect on the area under the ROC curve. For example, a predictor (or set of predictors) would need an odds ratio as high as 16 (>2 SD) to lead to a substantial increase in the C-statistic.²⁷ Almost no test in common use for risk prediction or prognostication in cardiovascular medicine has an odds ratio in this range; high cholesterol, smoking, high blood pressure, and diabetes are all associated with odds ratios of less than 2 and thus have little individual impact at all on the area under the ROC curve. Consequently, sole reliance on the C-statistic as a method for developing and evaluating new biomarkers, at least in the setting of risk prediction, is insufficient.

Accuracy and Calibration

Discrimination is only one measure of model accuracy. The other important measure is calibration, or the ability of a predictive model to assign risk estimates accurately in comparison to the actual observed risk in the population being tested. Unlike discrimination, which is based solely on relative rankings of risk, calibration compares the risk predicted from a model or test with that actually observed.

For binary outcomes (such as disease or no disease), calibration is often evaluated with the Hosmer-Lemeshow test, which places individuals within categories of estimated risk by using the test biomarker or multivariable model and compares these estimates with the proportions actually observed. These “predicted” and “observed” probabilities can be compared with standard goodness-of-fit tests across categories of risk (e.g., across estimated quintiles or estimated deciles of risk). Calibration becomes particularly important when addressing a biomarker in different populations from the one in which it was originally developed. A biomarker may calibrate well in men but not in women or among whites but not among blacks. This consideration also applies to multimarker panels—such as the Framingham Risk Score, which calibrates well in whites but less well in other population groups. Newer risk models such as the Reynolds Risk Score (www.reynoldsriskscore.org) show improved calibration, as well as discrimination, when compared with the traditional Framingham model.²⁸

Risk Reclassification

To address the shortcoming of biomarker validation via the C-statistic alone, contemporary biomarker development programs for risk prediction now use a series of “reclassification statistics,” as initially developed by Cook and colleagues^{29,30} and refined by Pencina and associates.³¹ Rather than addressing whether a new biomarker of interest adds to the area under the ROC curve, reclassification addresses whether the biomarker can shift overall risk estimates upward or downward in a clinically meaningful way. Specifically, reclassification methods compare risk strata formed from prediction models with and without the new biomarker of interest and then determine which model leads to the most accurate classification of risk. Risk reclassification is particularly useful when actionable and clinically relevant risk categories already exist. For example, in primary cardiovascular prevention, 10-year estimated risk is often categorized as being less than 5%, 5% to 10%, 10% to 20%, or greater than 20%, and those above or below these cut points are frequently targeted for interventions such as aspirin and statin therapy. Thus a biomarker that reclassifies a proportion of individuals upward (or

downward) might well be highly effective for targeting (or avoiding) drug therapy, even if the overall effect on discrimination is modest.

Mere reclassification of an individual by a given biomarker does not provide sufficient evidence to support clinical use. Rather, an effective biomarker should correctly reclassify risk higher or lower and thus lead to more accurate overall risk assessment. The reclassification calibration (RC) statistic is a tool that tests how well the average predicted risk within a given cell agrees with the observed risk of individuals who actually experience the event. Accordingly, the RC statistic addresses whether the predicted risk estimates after reclassification (using the new biomarker) are more accurate than before reclassification (without the new biomarker). Superior reclassification occurs when the new prediction model places case individuals into higher-risk categories and places control individuals into lower-risk categories and when the net shift in these two effects is in the overall correct direction. This characteristic can be addressed by using the net reclassification index (NRI), analogous to a test of discrimination (the ability to separate cases from controls) in the context of a reclassification table.³¹ Broadly, the NRI does not depend as much on the actual predicted probabilities as on movement across a categorical risk border that is the result of the new probabilities predicted. When reclassification is not addressed across categories, an alternative measure called the integrated discrimination improvement (IDI) is used; the IDI is based on the Yates slope, or the difference in predicted probabilities among case and control individuals.³²

Despite their relatively recent introduction, reclassification statistics have rapidly become the standard for clinical evaluation of emerging biomarkers and alternative multibiomarker prediction panels.

External Validation and Impact Studies

External validation is a final but important test for any biomarker or biomarker panel when used for prognostication. External validation refers to the ability of the panel to function with clinically acceptable levels of sensitivity, specificity, discrimination, and calibration in external populations, distinct from the population used for generation of the panel. As Moons and coworkers pointed out, prognosis research and prognostic biomarkers differ from those used in diagnosis and screening.³³ Prognostic research involves three distinct phases in the development of multivariable prediction models. The first phase includes identification of relevant predictors, assignment of weights to the model, estimation of predictive performance, and optimization of fit. The second phase involves validation or formal testing of calibration and discrimination in new patient groups, which can be similar to those used in the development stage or purposely different. Finally, the third phase involves impact studies to quantify directly whether use of a prognostic model in daily practice actually changes physician behavior and decision making and whether this occurs in a net positive manner and is cost-effective. Prognostic impact studies also focus on the incremental usefulness of a given biomarker beyond simple clinical and nonclinical characteristics. Such studies tend to be less biologically driven than biomarker discovery work is and recognize that prediction does not necessarily involve a causal pathway.

A Practical Example: High-Sensitivity C-Reactive Protein, Lipids, and the Reynolds Risk Score

The use of hsCRP in clinical practice is an example of how biomarker development programs can move from pathophysiologic principles to clinical use and onward to multinational trials evaluating novel targets for vascular risk reduction. In 1997, hsCRP was shown in a prospective cohort of initially healthy individuals to predict future risk for a heart attack and stroke in men,³⁴ an observation externally validated and quickly extended to women.³⁵ Assay systems underwent rapid improvement such that by 2004, multiple commercial

hsCRP assays—reproducible, internally calibrated, and externally validated to improve assay precision—were clinically available. Multiple studies have shown that statins reduce hsCRP in a manner largely independent of reduction of LDL cholesterol,³⁶ thus suggesting that statins have both lipid-lowering and anti-inflammatory effects.³⁷ In 2006, Cook and coauthors reported the ability of hsCRP to correctly reclassify patients into improved vascular risk categories.²⁹ The addition of hsCRP to the family history and HbA1c was formally incorporated into the Reynolds Risk Score in 2008. This score was subsequently externally validated and shown to have superior calibration, discrimination, and reclassification over the more traditional Framingham Risk Score.²⁸ Using hsCRP to define a high-risk population in need of treatment, JUPITER (Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin) reported in 2008 that statin therapy (versus placebo) in those with elevated hsCRP but low levels of LDL cholesterol resulted in a 50% reduction in myocardial infarction and stroke and a 20% reduction in all-cause mortality.³⁸ By 2010, more than 50 prospective cohort studies evaluating hsCRP were subjected to a meta-analysis in which it was affirmed that the magnitude of vascular risk associated with a change of 1 SD in hsCRP was at least as large as that of a comparable change in cholesterol or blood pressure.³⁹ In an updated 2012 meta-analysis that evaluated clinical usefulness and risk prediction, found the change in C-statistic associated with hsCRP to be similar to the change in C-statistic associated with the use of total and HDL cholesterol.²⁴ On this basis, several national guidelines incorporated hsCRP screening in primary and secondary prevention,⁴⁰ and the FDA approved a labeling claim for the use of statin therapy in those with elevated hsCRP levels.

CRP itself, however, probably does not cause atherothrombosis but rather serves as a biomarker for the underlying inflammatory process. Thus as a direct outcome of the hsCRP development program, two randomized trials have been initiated to directly test whether lowering inflammation per se can reduce vascular risk. These two trials—the NIH-funded CIRT (Cardiovascular Inflammation Reduction Trial), which evaluated low-dose methotrexate, and CANTOS (Canakinumab Anti-inflammatory Thrombosis Outcomes Study), which evaluated interleukin-1 β inhibition—are ongoing and, when complete, will have involved more than 18,000 patients worldwide.⁴¹

CONCLUSION

We use biomarkers in our daily clinical practice, and cardiovascular journals contain numerous reports regarding biomarkers, new and old, that purport to show how they may aid clinical practice. Moreover, many cardiovascular trials use biomarkers—hence the current practice of cardiovascular medicine requires a firm foundation in understanding and evaluating biomarkers. The road map to the field of biomarkers provided in this chapter—including their use, development, and methods for evaluating their usefulness for various specific applications—should give practitioners tools to sort out the various uses of biomarkers encountered in practice and in the cardiovascular literature.

Informed use of biomarkers can aid in decision making in daily patient care. Biomarkers should provide a key for personalized management by directing the right therapy to the right patient at the right time. They can also shed mechanistic insight on human pathophysiology that is difficult to obtain in other ways. Rigorous and careful use of biomarkers can aid in the development of novel therapies to address the residual burden of cardiovascular risk.

Evaluation of the patient with known or suspected cardiovascular disease begins with a directed history and targeted physical examination, the scope of which depends on the clinical context of the patient encounter. Elective, ambulatory investigations allow comparatively more time for the development of a comprehensive assessment, whereas emergency department visits and urgent bedside consultations necessitate a more focused strategy. The elicitation of the history, with its emphasis on major cardiovascular symptoms and their change over time, demands a direct interaction, neither delegated nor inferred from information gleaned from a cursory chart review. The history also affords a unique opportunity to assess the patient’s personal attitudes, intelligence, comprehension, acceptance or denial, motivation, fear, and prejudices. Such insights allow a more informed understanding of the patient’s preferences and values regarding shared decision making. The interview also can reveal genetic or familial influences and the impact of other medical conditions on the manifesting illness. Although time constraints have limited the emphasis on careful history taking,¹ the information gathered from the patient interview remains essential to inform the design of a resource-sensitive diagnostic and treatment plan.

Physical examination skills also have declined. Only a minority of internal medicine and family practice residents recognize classic cardiac findings in relevant diseases. Performance does not predictably improve with experience.² Residency work hours and health care system efficiency standards have severely restricted the time and expertise devoted to the mentored cardiovascular examination. In turn, less attention to bedside skills has increased the use of noninvasive imaging. Educational efforts, including repetition, patient-centered teaching conferences, and visual display feedback of auscultatory and Doppler echocardiographic findings, can improve performance.³⁻⁵

The evidence base that justifies correlations between history and physical examination findings and cardiovascular disease severity and prognosis has been most rigorously established for heart failure, valvular heart disease, and coronary artery disease. For example, vital signs and detection of pulmonary congestion and mitral

regurgitation (MR) contribute importantly to bedside risk assessment in patients with acute coronary syndromes (ACSs).^{6,7} The diagnosis of heart failure in ambulatory patients derives from attention to three basic elements of the history and six elements of the physical examination. The three important features of the history are dyspnea at one flight of stairs, orthopnea, and paroxysmal nocturnal dyspnea. The six elements of the physical examination that have undergone validation are a displaced apex beat, rales, an irregularly irregular pulse, a heart murmur suggestive of MR, a heart rate greater than 60 beats/min, and an elevated jugular venous pressure (JVP).⁸ Accurate auscultation provides important insight into many valvular and congenital heart lesions.⁹

This chapter reviews the fundamentals of the cardiovascular history and physical examination in light of the evidence base from correlative studies. See earlier editions of this book for further details.

THE HISTORY

The major signs and symptoms associated with cardiac disease include chest discomfort, dyspnea, fatigue, edema, palpitations, and syncope. In most cases, careful attention to the specific characteristics of chest discomfort—quality, location, radiation, triggers, mode of onset, and duration—along with alleviating factors and associated symptoms can narrow the differential diagnosis (see also [Chapter 50](#)). Cough, hemoptysis, and cyanosis also can contribute in this regard. Claudication, limb pain, edema, and skin discoloration usually indicate a vascular disorder. The cardiovascular clinician also should be familiar with common manifestations of acute stroke and transient ischemic attack, such as sudden weakness, sensory loss, incoordination, and visual disturbance. Angina pectoris must be differentiated from the pain associated with pulmonary embolism, pericarditis, aortic dissection, esophageal reflux, or costochondritis.

Several aspects of the presenting symptom of chest pain increase or decrease the likelihood of ACS. For example, pain that is sharp (likelihood ratio [LR], 0.3; 95% CI, 0.2 to 0.5), pleuritic (LR, 0.2; 95%

**TABLE 11-1 Comparison of Three Methods of Assessing Cardiovascular Disability**

CLASS	NYHA FUNCTIONAL CLASSIFICATION	CCS FUNCTIONAL CLASSIFICATION	SPECIFIC ACTIVITY SCALE
I	Patients with cardiac disease but without resulting limitations of physical activity Ordinary physical activity does not cause undue fatigue, palpitation, dyspnea, or anginal pain.	Ordinary physical activity, such as walking and climbing stairs, does not cause angina. Angina occurs with strenuous or rapid or prolonged exertion at work or recreation.	Patients can perform to completion any activity requiring >7 METs (e.g., can carry 24 lb up eight steps; carry objects that weigh 80 lb; do outdoor work [shovel snow, spade soil]; do recreational activities [skiing, basketball, squash, handball, jog/walk at 5 mph]).
II	Patients with cardiac disease resulting in slight limitation of physical activity They are comfortable at rest. Ordinary physical activity results in fatigue, palpitation, dyspnea, or angina pain.	Slight limitation of ordinary activity Walking or climbing stairs rapidly, walking uphill, walking or stair climbing after meals, in cold, in wind, or when under emotional stress, or only during the few hours after awakening Walking more than two blocks on the level and climbing more than one flight of ordinary stairs at a normal pace and in normal conditions	Patients can perform to completion any activity requiring >5 METs (e.g., have sexual intercourse without stopping, garden, rake, weed, rollerskate, dance [fox trot], walk at 4 mph on level ground), but cannot and do not perform to completion activities requiring ≥ 7 METs.
III	Patients with cardiac disease resulting in marked limitation of physical activity They are comfortable at rest. Less than ordinary physical activity causes fatigue, palpitation, dyspnea, or anginal pain.	Marked limitation of ordinary physical activity Walking one to two blocks on the level and climbing more than one flight of ordinary stairs in normal conditions	Patients can perform to completion any activity requiring >2 METs (e.g., shower without stopping, strip and make bed, clean windows, walk 2.5 mph, bowl, play golf, dress without stopping) but cannot and do not perform to completion any activities requiring ≥ 5 METs.
IV	Patients with cardiac disease resulting in inability to carry on any physical activity without discomfort Symptoms of cardiac insufficiency or of the anginal syndrome may be present even at rest. If any physical activity is undertaken, discomfort is increased.	Inability to carry on any physical activity without discomfort—anginal syndrome may be present at rest	Patients cannot or do not perform to completion activities requiring ≥ 2 METs. Cannot carry out activities listed for class III above.

MET = metabolic equivalents.

From Goldman L, Hashimoto B, Cook EF, Loscalzo A: Comparative reproducibility and validity of systems for assessing cardiovascular functional class: Advantages of a new specific activity scale. *Circulation* 64:1227, 1981.

CI, 0.1 to 0.3), positional (LR, 0.3; 95% CI, 0.2 to 0.5), or reproducible with palpation (LR, 0.3; 95% CI, 0.2 to 0.4) usually is noncardiac, whereas discomfort that radiates to both arms or shoulders (LR, 4.1; 95% CI, 2.5 to 6.5) or is precipitated by exertion (LR, 2.4; 95% CI, 1.5 to 3.8) has a higher likelihood of reflecting an ACS.¹⁰ Less classic symptoms (i.e., anginal equivalents) such as indigestion, belching, and dyspnea also should command the clinician's attention when other features of the presentation suggest ACS, even in the absence of chest discomfort. Women, elderly persons, and patients with diabetes more commonly present with a less typical clinical picture. Dyspnea may occur with exertion or in recumbency (orthopnea) or even on standing (platypnea). Paroxysmal nocturnal dyspnea of cardiac origin usually occurs 2 to 4 hours after onset of sleep; the dyspnea is of sufficient severity to compel the patient to sit upright or stand and then subsides gradually over several minutes. The patient's partner should be questioned about any signs of sleep-disordered breathing, such as loud snoring or periods of apnea. Pulmonary embolism often is associated with dyspnea of sudden onset.

Patients may use a variety of terms to describe their awareness of the heartbeat (palpitations), such as "flutters," "skips," or "pounding." The likelihood of a cardiac arrhythmia modestly increases with a known history of cardiac disease (LR, 2.03; 95% CI, 1.33 to 3.11) and decreases when symptoms resolve within 5 minutes (LR, 0.38; 95% CI, 0.22 to 0.63) or when associated with panic disorder (LR, 0.26; 95% CI, 0.07 to 1.01).¹¹ A report of a regular, rapid-pounding sensation in the neck (LR, 177; 95% CI, 25 to 1251) or visible neck pulsations associated with palpitations (LR, 2.68; 95% CI, 1.25 to 5.78) increases the likelihood that atrioventricular nodal reentrant tachycardia (AVNRT) is the responsible arrhythmia. The absence of a regular, rapid-pounding sensation in the neck makes detecting AVNRT much less likely (LR, 0.07; 95% CI, 0.03 to 0.19).¹² Cardiac syncope occurs suddenly, with rapid restoration of full consciousness thereafter. Patients with neurocardiogenic syncope may experience an early warning sign (nausea, yawning), appear ashen and diaphoretic, and revive more slowly, albeit without signs of seizure or a prolonged

postictal state. The complete history consists of information pertaining to traditional cardiovascular risk factors, a general medical history, occupation, social habits, medications, drug allergies or intolerance, family history, and systems review.

It is important to obtain a semiquantitative assessment of symptom severity and to document any change over time. The New York Heart Association (NYHA) and the Canadian Cardiovascular Society (CCS) functional classification systems are useful for both patient care and clinical research, despite their inherent limitations (Table 11-1).^{11,13}

THE GENERAL PHYSICAL EXAMINATION

The physical examination can help determine the cause of a given symptom, assess disease severity and progression, and evaluate the impact of specific therapies. It also can identify the presence of early-stage disease in patients without signs or symptoms.

General Appearance

The examination begins with an appreciation of the general appearance of the patient, including age, posture, demeanor, and general health status. Is the patient in pain, resting quietly, or visibly diaphoretic with a foreboding sense of doom? Does the patient choose to avoid certain positions to reduce or eliminate pain? The pain of acute pericarditis, for example, often diminishes with sitting up, leaning forward, or breathing shallowly. Pursing of the lips, a breathy quality to the voice, and an increased anteroposterior chest diameter would favor a pulmonary rather than a cardiovascular cause of dyspnea, although disorders in both etiologic categories may contribute in an individual patient. Pallor suggests anemia as a possible underlying disorder in patients with exercise intolerance or dyspnea, independent of cardiovascular disease. Cyanosis and jaundice also bear noting. Specific genetic cardiovascular disorders may be discernible from the patient's appearance. Emaciation suggests chronic heart

failure or another systemic disorder (e.g., malignancy, infection). The vital signs, including height, weight, temperature, pulse rate, blood pressure (in both arms), respiratory rate, and peripheral oxygen saturation, dictate the pace and scope of the evaluation and provide initial clues as to the presence of a cardiovascular disorder. The height and weight permit calculation of body mass index (BMI) and body surface area (BSA). Waist circumference (measured at the iliac crest) and waist-to-hip ratio (using the widest circumference around the buttocks) powerfully predict long-term cardiovascular risk.^{14,15} In patients with palpitations, a resting heart rate less than 60 beats/min may increase the likelihood of a clinically significant arrhythmia (LR, 3.00; 95% CI, 1.27 to 7.08).¹¹ Observation of the respiratory pattern may reveal signs of disordered breathing (e.g., Cheyne-Stokes respirations, obstructive sleep apnea), a finding associated with reduced survival in patients with severe systolic heart failure.¹⁶ Mental status should be assessed.

Skin

Central cyanosis is present with significant right-to-left shunting at the level of the heart or lungs. It also is a feature of hereditary methemoglobinemia. Peripheral cyanosis or acrocyanosis of the fingers, toes, nose, and ears is characteristic of the reduced blood flow that accompanies small-vessel constriction seen in severe heart failure, shock, or peripheral vascular disease. Differential cyanosis affecting the lower but not the upper extremities occurs with a patent ductus arteriosus (PDA) and pulmonary artery hypertension with right-to-left shunting at the great vessel level. Hereditary telangiectases on the lips, tongue, and mucous membranes (a finding in Osler-Weber-Rendu syndrome) resemble spider nevi; when present in the lungs, they can cause right-to-left shunting and central cyanosis. Telangiectasias also are seen in patients with scleroderma with or without pulmonary hypertension. Tanned or bronze discoloration of the skin in unexposed areas can suggest iron overload and hemochromatosis. With jaundice, often first appreciated in the sclerae, the differential diagnosis is broad in scope. Ecchymoses often occur with either anticoagulant and/or antiplatelet use, whereas petechiae characterize thrombocytopenia, and purpuric skin lesions can be seen with infective endocarditis and other causes of leukocytoclastic vasculitis. Various lipid disorders can manifest with xanthomas, located subcutaneously, along tendon sheaths, or over the extensor surfaces of the extremities. Xanthomas within the palmar creases are specific for type III hyperlipoproteinemia. The leathery, cobblestone, “plucked chicken” appearance of the skin in the axillae and skinfolds of a young person is characteristic of pseudoxanthoma elasticum, a disease with multiple cardiovascular manifestations, including premature atherosclerosis.¹⁷ Extensive lentiginoses (freckle-like brown macules and café-au-lait spots over the trunk and neck) may be part of developmental delay–associated cardiovascular syndromes (LEOPARD, LAMB, and Carney) with multiple atrial myxomas, atrial septal defect (ASD), hypertrophic cardiomyopathy, and valvular stenoses. In a patient with heart failure or syncope, cardiovascular sarcoid should be suspected in the presence of lupus pernio, erythema nodosum, or granuloma annulare. Certain vascular disorders such as erythromelalgia or lymphangitis also may be readily apparent from examination of the skin.

Head and Neck

All patients should undergo assessment of the state of dentition, both as a source of infection and as an index of general health and hygiene. A high-arched palate is a feature of Marfan and other connective tissue disease syndromes. A large protruding tongue with parotid enlargement may suggest amyloidosis. A bifid uvula has been described in patients with Loeys-Dietz syndrome. Orange tonsils are characteristic of Tangier disease. Ptosis and ophthalmoplegia suggest muscular dystrophies, and congenital heart disease often is accompanied by hypertelorism, low-set ears, micrognathia, and a webbed neck, as with Noonan, Turner, and Down syndromes. Proptosis, lid lag, and stare point to Graves hyperthyroidism. Blue sclerae, mitral

or aortic regurgitation (AR), and a history of recurrent nontraumatic skeletal fractures are observed in patients with osteogenesis imperfecta.

Attention to the extraocular movements and the size and symmetry of the pupils may reveal a neurologic disorder. The oft-omitted fundoscopic examination can aid in the evaluation of patients with hypertension, atherosclerosis, diabetes, endocarditis, neurologic signs or symptoms, or known carotid or aortic arch disease. Lacrimal gland hyperplasia is sometimes a feature of sarcoidosis. The “mitral facies” of rheumatic mitral stenosis (pink-purplish patches with telangiectasias over the malar eminences) also can accompany other disorders associated with pulmonary hypertension and reduced cardiac output. Relapsing polychondritis is suggested by inflammation of the pinnae and nasal cartilage in association with a saddle-nose deformity. Palpation of the thyroid gland assesses its size, symmetry, and consistency. In some patients, earlier treatment with mantle irradiation for lymphoma can lead to a “dropped head myopathy,” characterized by loss of the anterior cervical strap muscles and permanent forward flexion.

Extremities

The temperature of the extremities and the presence of clubbing, arachnodactyly, and nail changes can be quickly ascertained. Clubbing implies the presence of central shunting (**Fig. 11-1**). The unopposable “fingerized” thumb occurs in Holt-Oram syndrome. Arachnodactyly characterizes the Marfan syndrome. Janeway lesions (nontender, slightly raised areas of hemorrhage on the palms and soles), Osler’s nodes (tender, raised nodules on the pads of the fingers or toes), and splinter hemorrhages (linear petechiae in the mid-nailbed) may be signs of infective endocarditis.

Lower extremity or presacral edema with elevated JVP occurs in many volume-overloaded states, including heart failure. With a normal JVP, additional signs of venous disease, such as extensive varicosities, medial ulcers, or brownish pigmentation from hemosiderin deposition, suggest chronic venous insufficiency. Edema also can occur with dihydropyridine calcium channel blocker therapy. Anasarca seldom occurs in heart failure, unless the condition is long standing, untreated, and accompanied by hypoalbuminemia. Asymmetric swelling can reflect local or unilateral venous thrombosis, the sequelae of previous vein graft harvesting, or lymphatic obstruction. Homan’s sign (calf pain elicited by forceful dorsiflexion of the foot) is neither specific nor sensitive for deep vein thrombosis. Muscular atrophy and the absence of hair in an extremity should suggest chronic arterial insufficiency or a neuromuscular disorder. Redistribution of fat from the extremities to central/abdominal stores (lipodystrophy) in some patients with HIV infection may relate to antiretroviral treatment, and is associated with insulin resistance and several features of the metabolic syndrome.

Chest and Abdomen

Cutaneous venous collaterals over the anterior chest suggest chronic obstruction of the superior vena cava (SVC) or subclavian vein, especially in the presence of indwelling catheters or leads. Asymmetric breast enlargement unilateral to an implanted device also may be present. Thoracic cage abnormalities, such as pectus carinatum (pigeon chest) or pectus excavatum (funnel chest), may accompany connective tissue disorders; the barrel chest of emphysema or advanced kyphoscoliosis may be associated with cor pulmonale. The severe kyphosis of ankylosing spondylitis should prompt careful auscultation for AR. The “straight back syndrome” (loss of normal kyphosis of the thoracic spine) can accompany mitral valve prolapse (MVP). A thrill may be present over well-developed intercostal artery collaterals in patients with aortic coarctation.

Patients with emphysema may exhibit prominence of the cardiac impulse in the epigastrium. The liver often is enlarged and tender in heart failure; systolic hepatic pulsations signify severe tricuspid regurgitation (TR). Patients with infective endocarditis of long duration may have splenomegaly. Ascites can develop with advanced and

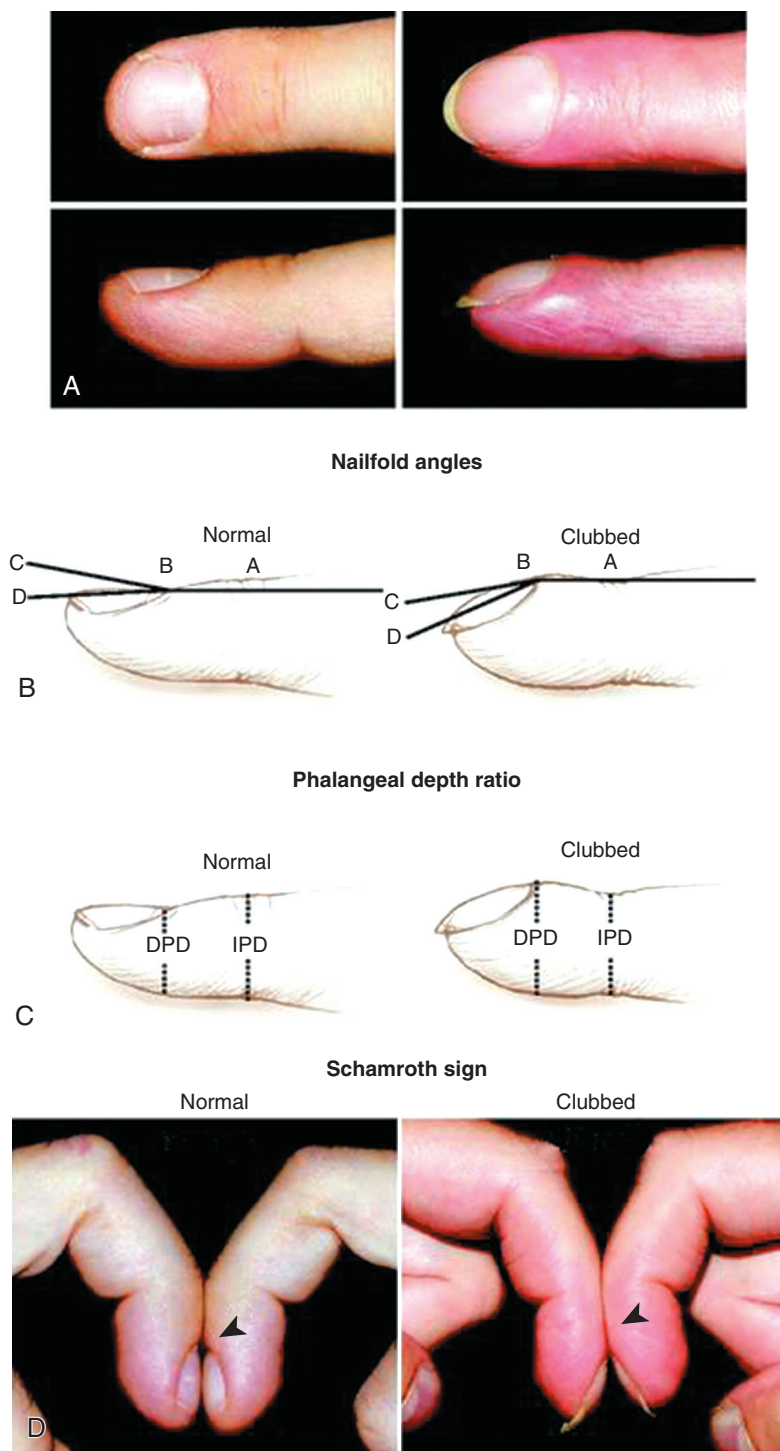

FIGURE 11-1 **A**, Normal finger and a finger with the changes characteristic of established clubbing, viewed from above and in profile. **B**, The finger on the *left* demonstrates normal profile (ABC) and normal hyponychial (ABD) nailfold angles of 169 degrees and 183 degrees, respectively. The clubbed finger on the *right* shows increased profile and hyponychial nailfold angles of 191 degrees and 203 degrees, respectively. **C**, Distal phalangeal finger depth (DPD)/interphalangeal finger depth (IPD) represents the phalangeal depth ratio. In normal fingers, the IPD is greater than the DPD. In clubbing, this relationship is reversed. **D**, Schamroth sign: In the absence of clubbing, nail-to-nail opposition creates a diamond-shaped window (*arrowhead*). In clubbed fingers, the loss of the profile angle with the increase in tissue at the nail bed causes obliteration of this space (*arrowhead*). (From Myers KA, Farquhar DR: Does this patient have clubbing? JAMA 286:341, 2001.)

chronic right heart failure or constrictive pericarditis. The abdominal aorta normally may be palpated between the epigastrium and the umbilicus in thin patients and in children. The sensitivity of palpation for the detection of abdominal aortic aneurysm (AAA) disease increases as a function of aneurysm diameter and varies inversely

with body size. Arterial bruits in the abdomen should be sought.

THE CARDIOVASCULAR EXAMINATION

Jugular Venous Pressure and Waveform

The JVP aids in the estimation of volume status. The external (EJV) or internal (IJV) jugular vein may be used, although the IJV is preferred because the EJV is valved and not directly in line with the SVC and right atrium. The EJV is easier to visualize when distended, and its appearance can help to discriminate between low and high central venous pressure (CVP). An elevated left EJV pressure may also signify a persistent left-sided SVC or compression of the innominate vein from an intrathoracic structure. If an elevated CVP is suspected but venous pulsations cannot be appreciated, the patient should be asked to sit with the feet dangling. With subsequent pooling of blood in the lower extremities, venous pulsations may be evident. SVC syndrome should be suspected if the venous pressure is elevated, pulsations are still not discernible, and the skin of the head and neck appears dusky or cyanotic. When hypovolemia is suspected as a cause of hypotension, the patient may need to be lowered to a supine position to gauge the waveform in the right supraclavicular fossa.

The venous waveform can sometimes be difficult to distinguish from the carotid artery pulse. The venous waveform has several characteristic features (**Fig. 11-2**; **Table 11-2**) and its individual components can usually be identified. The *a* and *v* waves, and *x* and *y* descents, are defined by their temporal relation to electrocardiographic events and heart sounds (*S*₁ and *S*₂, plus *S*₃ and *S*₄ as defined further on). The estimated height of the venous pressure indicates the CVP or right atrial pressure. Although observers vary widely in estimation of the CVP, knowledge that the pressure is elevated, and not its specific value, can inform diagnosis and management.

The venous pressure is measured as the vertical distance between the top of the venous pulsation and the sternal inflection point, where the manubrium meets the sternum (angle of Louis). A distance of greater than 3 cm is considered abnormal, but the distance between the angle of Louis and the mid-right atrium varies considerably, especially in obese patients. On chest computed tomography (CT) scans in 160 consecutive patients, this distance varied considerably in accordance with body position.¹⁸ In general, use of the sternal angle as a reference leads to systematic underestimation of venous pressure. In practice, however, it is difficult to use even relatively simple landmarks, and on attempts to locate an external reference point to determine the CVP, measurements obtained by critical care nurses vary by several centimeters. Venous pulsations above the clavicle with the patient in the sitting position are clearly abnormal, because the distance from the right atrium is at least 10 cm. Estimated CVP correlates only modestly with direct measurement. Measurements made at the bedside, in units of centimeters of blood or water, require conversion to millimeters of mercury (1.36 cm H₂O = 1.0 mm Hg), for comparison with values measured with catheterization.

The venous waveforms include several distinct peaks: *a*, *c*, and *v* (see **Fig. 11-2**). The *a* wave reflects right atrial presystolic contraction, occurs just after the electrocardiographic P wave, and precedes the first heart sound (*S*₁). Patients with reduced right ventricular (RV) compliance from any cause can have a prominent *a* wave. A cannon *a* wave occurs with atrioventricular (AV)

FIGURE 11-2 The normal jugular venous waveform recorded at cardiac catheterization. Note the inspiratory fall in pressure and the dominant x/x' descent.

TABLE 11-2 Distinguishing Jugular Venous Pulse from Carotid Pulse

FEATURE	INTERNAL JUGULAR VEIN PULSE	CAROTID ARTERY PULSE
Appearance of pulse	Undulating two troughs and two peaks for every cardiac cycle (biphasic)	Single brisk upstroke (monophasic)
Response to inspiration	Height of column falls and troughs become more prominent	No respiratory change to contour
Palpability	Generally not palpable (except in severe TR)	Palpable
Effect of pressure	Can be obliterated with gentle pressure at base of vein/clavicle	Cannot be obliterated

TR = tricuspid regurgitation.

dissociation and right atrial contraction against a closed tricuspid valve (**Fig. 11-3**). The presence of cannon a waves in a patient with wide complex tachycardia identifies the rhythm as ventricular in origin. The a wave is absent with atrial fibrillation (AF). The x descent reflects the fall in right atrial pressure after the a wave peak. The c wave interrupts this descent as ventricular systole pushes the closed valve into the right atrium. In the neck, the carotid pulse also may contribute to the c wave. As depicted in **Figure 11-3**, the x' descent follows because of atrial diastolic suction created by ventricular systole pulling the tricuspid valve downward. In normal persons, the x' descent is the predominant waveform in the jugular venous pulse. The v wave represents atrial filling, occurs at the end of ventricular systole, and follows just after S_2 . Its height is determined by right atrial compliance and by the volume of blood returning to the right atrium from any source. The v wave is smaller than the a wave because of the normally compliant right atrium. In patients with ASD, the a and v waves may be of equal height; in TR, the v wave is accentuated (**Video 11-1**). With TR, the v wave will merge with the c wave because retrograde valve flow and antegrade right atrial filling occur simultaneously (see **Fig. 11-3**). The y descent follows the v wave peak and reflects the fall in right atrial pressure after tricuspid valve opening. Resistance to ventricular filling in early diastole blunts the y descent, as is the case with pericardial tamponade or tricuspid stenosis. The y descent will be steep when ventricular diastolic filling occurs early and rapidly, as with pericardial constriction or isolated, severe TR. The normal venous pressure should fall by at least 3 mm Hg with

inspiration. A rise in venous pressure (or its failure to decrease) with inspiration (Kussmaul sign) is associated with constrictive pericarditis, and also with restrictive cardiomyopathy, pulmonary embolism, RV infarction, and advanced systolic heart failure. A Kussmaul sign (**Video 11-2**) is seen with right-sided volume overload and reduced RV compliance. Normally, the inspiratory increase in right-sided venous return is accommodated by increased RV ejection, facilitated by an increase in the capacitance of the pulmonary vascular bed. In states of RV diastolic dysfunction and volume overload, the right ventricle cannot accommodate the enhanced volume, and the pressure rises.

The abdominojugular reflex or passive leg elevation can elicit venous hypertension. The abdominojugular reflex requires firm and consistent pressure over the upper abdomen, preferably the right upper quadrant, for at least 10 seconds. A sustained rise of more than 3 cm in the venous pressure for at least 15 seconds after resumption of spontaneous respiration is a positive response. The patient should be coached to refrain from holding the breath or

performing a Valsalva-like maneuver, which can falsely elevate the venous pressure. The abdominojugular reflex can predict heart failure and a pulmonary artery wedge pressure higher than 15 mm Hg.¹⁹

Measuring the Blood Pressure

Auscultatory measurement of blood pressure (see also **Chapter 43**) yields lower systolic and higher diastolic values than direct intra-arterial recording.²⁰ Nurse-recorded blood pressure usually is closer to the patient's average daytime blood pressure. Blood pressure should be measured with the patient in the seated position, with the arm at the level of the heart, using an appropriate-size cuff (**Table 11-3**). The use of an inappropriately small cuff can result in overestimation of the true blood pressure, an issue of particular relevance in obese patients.

On occasion, the Korotkoff sounds may disappear soon after the first sound, only to recur later before finally disappearing as phase 5. This auscultatory gap is more likely to occur in older, hypertensive patients with target organ damage. The systolic pressure should be recorded at the first Korotkoff sound and not when the sound reappears. This finding should be distinguished from *pulsus paradoxus* (see later). Korotkoff sounds may be heard all the way down to 0 mm Hg with the cuff completely deflated in children, in pregnant patients, or in patients with chronic severe AR, or in the presence of a large arteriovenous fistula. In these cases, both the phase 4 and phase 5 pressures should be noted.

Blood pressure should be measured in both arms either in rapid succession or simultaneously; normally the measurements should differ by less than 10 mm Hg, independent of handedness. As many as 20% of normal subjects, however, exhibit a left-right arm blood pressure differential of more than 10 mm Hg in the absence of symptoms or other examination findings. A blood pressure differential of more than 10 mm Hg can be associated with subclavian artery disease, supraaortic stenosis, aortic coarctation, or aortic dissection. Systolic leg pressures may exceed arm pressures by as much as 20 mm Hg; greater leg-arm systolic blood pressure differences are seen in patients with severe AR (Hill sign) and patients with extensive and calcified lower extremity peripheral arterial disease (PAD). Leg blood pressure should be measured using large thigh cuffs with auscultation at the popliteal artery or using a standard large arm cuff on the calf with simultaneous auscultation or palpation at the posterior tibial artery (**Fig. 11-4**). Measurement of lower extremity blood pressures constitutes the basis of the ankle-brachial index (ABI) (see **Chapter 58**).

**VIDEO 11-1**

V wave. Dramatic V wave is visible in the left neck of a patient with severe tricuspid regurgitation as complication of pulmonary arterial hypertension. Inspection of the right neck alone would underestimate the severity of tricuspid regurgitation and venous pressure.

VIDEO 11-2

Kussmaul sign. Kussmaul sign in a patient with chronic biventricular heart failure. With inspiration, the height of the V wave increases and the depth of the subsequent Y descent increases. This finding occurs when the diastolic compliance of the right ventricle cannot accommodate the respiratory increase in the venous return.

FIGURE 11-3 Abnormal jugular venous waveforms. **A**, Large *a* waves associated with reduced RV compliance or elevated RV end-diastolic pressure. Phonocardiographic tracing (below) shows timing of the corresponding right-sided *S*₄. **B**, Normal jugular venous waveform (bottom), mild TR (middle), and severe TR (top), with corresponding phonocardiogram. With severe TR, “ventricularization” of the jugular venous waveform is seen, with a prominent *v* wave and rapid *y* descent. The *x* descent is absent. **C**, Jugular venous waveform in constrictive pericarditis with a prominent *y* descent. Note the timing of the pericardial knock (K) relative to *S*₂. The abrupt rise in pressure after the nadir of the *y* descent is caused by the rapid rise in venous pressure with ventricular filling. JVP = jugular venous pulse. (From Abrams J: *Synopsis of Cardiac Physical Diagnosis*. 2nd ed. Boston, Butterworth Heinemann, 2001, pp 25-35.)

TABLE 11-3 Important Aspects of Blood Pressure Measurement

- Patient should be seated comfortably, with back supported and legs uncrossed and the upper arm bared.
- Upper arm should be at heart level.
- Cuff length and width should be 80% and 40% of arm circumference, respectively.
- Cuff should be deflated at <3 mm Hg/sec.
- Column or dial should be read to nearest 2 mm Hg.
- First audible Korotkoff sound is systolic pressure; last sound, diastolic pressure.
- There should be no talking between subject and observer (or other person).

Consideration should be given to ambulatory blood pressure monitoring when uncertainty exists about the significance of recordings obtained in the clinic. This approach is especially useful for the patient with suspected “white coat hypertension” (see Chapter 43).²¹ Measurement of normal or even low blood pressures in the face of evidence of hypertensive end organ damage should suggest masked hypertension caused by severe PAD.

Orthostatic hypotension (a fall in blood pressure of more than 20 mm Hg systolic and/or more than 10 mm Hg diastolic in response to moving from the supine to the standing position within 3 minutes) may be accompanied by a lack of compensatory tachycardia, a response suggestive of autonomic insufficiency, as can occur in patients with diabetes or Parkinson disease. The heart rate–blood pressure response to standing also depends on age, hydration, medications, food, conditioning, and ambient temperature and humidity.

An increase in pulse pressure can represent increased vascular stiffness, usually secondary to aging or atherosclerosis. Aortic stiffness is increased in patients with Marfan syndrome and other connective tissue disorders and may contribute to risk for dissection. Peripheral indices may not correlate well with central aortic stiffness, which is a primary determinant of ventricular-vascular coupling. One measure, the augmentation index, is the percentage increase in systolic pressure created by the premature return of the reflected wave during late systole.

Assessing the Pulses

The carotid artery pulse wave occurs within 40 milliseconds of the ascending aortic pulse and reflects aortic valve and ascending aortic function. The temporal arteries can be easily palpated to aid in the diagnosis of temporal arteritis. One of the two pedal pulses may not be palpable in a normal subject as a consequence of unusual anatomy (posterior tibial, less than 5%; dorsal pedis, less than 10%), but each pair should be symmetric. True congenital absence of a pulse is rare, and in most cases, pulses can be detected with a handheld Doppler device when not palpable. Simultaneous palpation of the brachial or radial pulse with the femoral pulse should be performed in patients with hypertension to screen for aortic coarctation.

The contour of the pulses depends on the stroke volume, ejection velocity, vascular capacity and compliance, and systemic resistance. The palpable pulse reflects the merging of the antegrade pulsatile flow of blood and reflection of the propagated pulse returning from the periphery. The amplitude of the arterial pulse increases with distance from the heart. Normally, the incident (percussion) wave begins with systolic ejection (just after *S*₁) and is the predominant monophasic pulse appreciated at the bedside (Fig. 11-5). The incisura or dicrotic notch identifies aortic valve closure. A *bounding* pulse may occur in hyperkinetic states such as fever, anemia, and thyrotoxicosis, or in pathologic states such as severe bradycardia, AR, or arteriovenous fistula. A *bifid* pulse is created by two distinct pressure peaks. This phenomenon may occur with fever or after exercise in a normal person and is consistent with increased vascular compliance. With chronic severe AR, a large stroke volume ejected rapidly into a noncompliant arterial tree produces a reflected wave of sufficient amplitude to be palpated during systole, rendering the pulse bifid. Hypertrophic obstructive cardiomyopathy (HOCM) can rarely produce a bifid systolic pulse with percussion and tidal waves (see Fig. 11-5).

A fall in systolic pressure of more than 10 mm Hg with inspiration (*pulsus paradoxus*) is considered pathologic and a sign of pericardial or pulmonary disease; this phenomenon also can occur in obesity²² and pregnancy without clinical disease. Pulsus paradoxus is detected by noting the difference between the systolic pressure at which the Korotkoff sounds are first heard (during expiration) and the systolic pressure at which the Korotkoff sounds are heard with each beat, independent of respiratory phase. Between these two pressures, the sounds will be heard only intermittently (during expiration). Appreciation of this finding requires a slow release of the cuff pressure. Conditions such as tachycardia, AF, and tachypnea make its assessment difficult. Pulsus paradoxus may be palpable when the pressure

FIGURE 11-4 Assessment of the lower extremity blood pressures. **A**, Anatomy of the major arteries of the lower limb; **B**, measurement of ankle systolic pressure. (From Khan NA, Rahim SA, Anand SS, et al: Does the clinical examination predict lower extremity peripheral arterial disease? JAMA 295:536, 2006.)

difference exceeds 15 to 20 mm Hg (see Chapter 71). Pulsus paradoxus is not specific for pericardial tamponade and can accompany massive pulmonary embolus, hemorrhagic shock, severe obstructive lung disease, or tension pneumothorax.

Pulsus alternans is defined by the beat-to-beat variability of the pulse amplitude (Fig. 11-6). It is present when only every other phase 1 Korotkoff sound is audible as the cuff pressure is slowly lowered, in a patient with a regular heart rhythm, independent of the respiratory cycle. Pulsus alternans generally occurs in severe heart failure, in severe AR, hypertension, and hypovolemic states. It is attributed to cyclic changes in intracellular calcium and action potential duration. Association with electrocardiographic T wave alternans appears to increase arrhythmic risk.²³

Severe aortic stenosis may be suggested by a weak and delayed pulse (*pulsus parvus et tardus*), and is best appreciated by careful palpation of the carotid arteries (see Fig. 11-5; see also Chapter 63). The delay is assessed during simultaneous auscultation of the heart sounds; the carotid upstroke should coincide with S₁. This finding is less specific in older, hypertensive patients with reduced vascular compliance and stiffer carotid arteries. An abrupt carotid upstroke with rapid fall-off characterizes the pulse of chronic AR (Corrigan or

water-hammer pulse). The carotid upstroke also is rapid in older patients with isolated systolic hypertension and wide pulse pressures.

Pulsation of the abdominal aorta can be appreciated in the epigastric area. Femoral and popliteal artery aneurysms should be sought in patients with AAA disease or underlying connective tissue disease.

The history and physical examination findings can help assess the level of arterial obstruction in patients with lower extremity claudication (see Chapter 58). Auscultation for aortic and femoral artery bruits should be routine. The correlation between the presence of a bruit and the degree of vascular obstruction is weak. Extension of a bruit into diastole or a thrill generally indicates severe obstruction. Other causes of a bruit include arteriovenous fistulas and enhanced flow through normal arteries as, for example, in a young patient with fever.

Integrating the clinical history and presence of atherosclerotic risk factors improves the accuracy of the examination for the identification of lower extremity PAD.²⁴ In an asymptomatic patient, the presence of a femoral bruit (LR, 4.8; 95% CI, 2.4 to 9.5) or any abnormality of the pulse (LR, 3.1; 95% CI, 3.1 to 6.6) increases the likelihood of PAD. The likelihood of significant PAD increases when there are

lower extremity symptoms and cool skin (LR, 5.9; 95% CI, 4.1 to 8.6), pulse abnormalities (LR, 4.7; 95% CI, 2.2 to 9.9), or any bruit (LR, 5.6; 95% CI, 4.7 to 6.7) (Table 11-4). Abnormal pulse oximetry, defined by a more than 2% difference between finger and toe oxygen saturation, can also indicate lower extremity PAD and is comparable to the ABI (LR, 30.0; 95% CI, 7.6 to 121 versus LR, 24.8; 95% CI, 6.2 to 99.8).²⁵

FIGURE 11-5 Carotid pulse waveforms and heart sounds. **A**, Normal. **B**, Aortic stenosis. Anacrotic pulse with slow upstroke and peak near S_2 . **C**, Severe AR: bifid pulse with two systolic peaks. The second peak (tidal or reflected wave) is of lower amplitude than the initial percussion wave. **D**, Hypertrophic obstructive cardiomyopathy (HOCM): bifid pulse with two systolic peaks. The second peak (tidal or reflected wave) is of lower amplitude than the initial percussion wave. **E**, Bifid pulse with systolic and diastolic peaks as may occur with sepsis or intra-aortic balloon counterpulsation. A_2 = aortic component of S_2 ; P_2 = pulmonic component of S_2 . (From Chatterjee K: *Bedside evaluation of the heart: the physical examination*. In Braunwald E, Goldman L [eds]: *Primary Cardiology*. 2nd ed. Philadelphia, WB Saunders, 2003, p 36.)

Inspection and Palpation of the Heart

The apical heartbeat may be visible in thin-chested adults. The left anterior chest wall may heave in patients with enlarged and hyperdynamic left ventricles. Right upper parasternal and sternoclavicular pulsations suggest ascending aortic aneurysm disease. A left parasternal lift indicates RV pressure or volume overload. A pulsation in the third intercostal space to the left of the sternum can indicate pulmonary artery hypertension. In very thin, tall patients, or in patients with emphysema and flattened diaphragms, the RV impulse may be visible in the epigastrium and should be distinguished from a pulsatile liver edge.

Palpation of the heart should begin with the patient in the supine position inclined at 30 degrees. If the heart is not palpable in this position, the patient should be examined either in the left lateral decubitus position with the left arm above the head or in the seated position, leaning forward. The point of maximal impulse normally is over the left ventricular (LV) apex beat and should be located in the midclavicular line at the fifth intercostal space. It is smaller than 2 cm in diameter and moves quickly away from the fingers. It is best appreciated at end-expiration, when the heart is closest to the chest wall. The normal impulse may not be palpable in obese or muscular patients or in those with thoracic cage deformities. LV cavity enlargement displaces the apex beat leftward and downward. A sustained apex beat is a sign of LV pressure overload (as in aortic stenosis or hypertension). A palpable, presystolic impulse corresponds to a fourth heart sound (S_4) and reflects the atrial contribution to ventricular diastolic filling of a noncompliant left ventricle. A prominent, rapid early filling wave in patients with advanced systolic heart failure may result in a palpable third sound (S_3), which may be present when the gallop itself is not audible (Video 11-3). A large ventricular aneurysm may yield a palpable and visible ectopic impulse discrete from the apex beat. HOCM rarely may cause a triple cadence apex beat, with contributions from a palpable S_4 and the two components of the systolic pulse.

A parasternal lift occurs with RV pressure or volume overload. Signs of TR (jugular venous *cv* waves) and/or pulmonary artery hypertension (loud, single, or palpable P_2) should be sought. An enlarged RV can give rise to a precordial lift that can extend across the precordium and obscure left-sided findings. Rarely, patients with severe MR will have a prominent left parasternal impulse because of systolic expansion of the left atrium and forward displacement of the heart. Lateral retraction of the chest wall may be present with isolated RV enlargement secondary to posterior displacement of the systolic LV impulse. Systolic and diastolic thrills signify turbulent, high-velocity blood flow. Their locations help to identify the origins of heart murmurs.

Auscultation of the Heart

Heart Sounds

First Heart Sound (S_1)

The normal first heart sound (S_1) comprises mitral (M_1) and tricuspid (T_1) valve closure. The two components usually are best heard at the lower left sternal border in younger subjects. Normal splitting of S_1 is accentuated with complete right bundle branch block. S_1 intensity increases in the early stages of rheumatic mitral stenosis when the valve leaflets are still pliable, in hyperkinetic states, and with short P-R intervals (less than 160 milliseconds). S_1 becomes softer in the late stages of stenosis, when the leaflets are rigid and calcified, with contractile dysfunction, beta-adrenergic receptor blockers, and long P-R intervals (greater than 200 milliseconds). Other factors that can decrease the intensity of the heart sounds and murmurs include mechanical ventilation, obstructive lung disease, obesity, pendulous breasts, pneumothorax, and pericardial effusion.

FIGURE 11-6 Pulsus alternans in a patient with severe left ventricular systolic dysfunction. The systolic pressure varies from beat to beat, independent of the respiratory cycle. The rhythm is sinus throughout.

**VIDEO 11-3**

Precordial diastolic gallop. Palpable and visible precordial diastolic gallop in a patient with dilated cardiomyopathy is amplified by the placement of a tongue depressor over the point of maximal impulse. The tip of the tongue depressor “vibrates” with the occurrence of the systolic impulse and diastolic gallop. Precordial gallops are often palpable even when inaudible with auscultation.

TABLE 11-4 Likelihood Ratios for Various Symptoms or Signs of Peripheral Arterial Disease*

Type of Study by Symptom/Sign	Severity	Clinical Finding	Likelihood Ratio (with 95% CI)	
			Positive	Negative
Claudication				
Screening	Any level of disease	“Definite” or “probable” claudication	3.30 (2.30-4.80) [†]	
	Moderate to severe	No claudication		0.57 (0.43-0.76)
	Any level of disease	No claudication		0.89 (0.78-1.00)
Skin Changes				
Symptomatic	Any level of disease	Cooler to touch	5.90 (4.10-8.60)	0.92 (0.89-0.95)
		Wounds or sores	5.90 (2.60-13.40)	0.98 (0.97-1.00)
		Discoloration	2.80 (2.40-3.30)	0.74 (0.69-0.79)
Screening	Moderate to severe	Hair, temperature, color, or atrophic change	1.50 (1.20-1.70) [†]	0.81 (0.72-0.92) [†]
Bruits				
Symptomatic	Any level of disease	At least one bruit (iliac, femoral, popliteal)	5.60 (4.70-6.70) [†]	0.39 (0.34-0.45) [†]
	Any level of disease	Femoral bruit	5.70 (4.70-7.00)	0.74 (0.70-0.78)
Screening	Any level of disease	Femoral bruit	4.80 (2.40-9.50)	0.83 (0.73-0.95)
Pulse Palpation				
Symptomatic	Any level of disease	Any palpable pulse abnormality	4.70 (2.20-9.90)	0.38 (0.23-0.64)
Screening	Moderate to severe	Any palpable pulse abnormality	3.00 (2.30-3.90)	0.44 (0.30-0.66)
	Any level of disease	Any palpable pulse abnormality	3.10 (1.40-6.60)	0.48 (0.22-1.04)
	Any level of disease	Absence of any palpable abnormality (in a lipid research clinic study)		0.27 (0.16-0.44)
	Any level of disease	Absence of any palpable abnormality (in high prevalence of diabetes)		0.87 (0.79-0.97)

*Stratified by symptomatic or screening studies.

[†]Results statistically homogeneous (all $P > 0.20$). Moderate to severe peripheral arterial disease defined by ankle-brachial index <0.50 .Modified from Khan NA, Rahim SA, Anand SS, et al: Does the clinical examination predict lower extremity peripheral arterial disease? *JAMA* 295:536, 2006.

Second Heart Sound (S_2)

The second heart sound (S_2) comprises aortic (A_2) and pulmonic (P_2) valve closure. With normal, or physiologic, splitting, the A_2 - P_2 interval increases during inspiration and narrows with expiration. The individual components are best heard at the second left interspace with the patient in the supine position. The A_2 - P_2 interval widens with complete right bundle branch block because of delayed pulmonic valve closure, and with severe MR because of premature aortic valve closure. Unusually narrow but physiologic splitting of S_2 , with an increase in the intensity of P_2 relative to A_2 , indicates pulmonary artery hypertension. With fixed splitting, the A_2 - P_2 interval is wide and remains unchanged during the respiratory cycle, indicating ostium secundum ASD. Reverse, or paradoxical, splitting occurs as a consequence of a pathologic delay in aortic valve closure, as may occur with complete left bundle branch block, RV apical pacing, severe aortic stenosis, HOCM, and myocardial ischemia. A_2 normally is louder than P_2 and can be heard at most sites across the precordium. When both components can be heard at the lower left sternal border or apex, or when P_2 can be palpated at the second left interspace, pulmonary hypertension is present. The intensity of A_2 and P_2 decreases with aortic and pulmonic stenosis, respectively. A single S_2 may result.

Systolic Sounds

An ejection sound is a high-pitched, early systolic sound that coincides in timing with the upstroke of the carotid pulse and usually is associated with congenital bicuspid aortic or pulmonic valve disease, or sometimes with aortic or pulmonic root dilation and normal semilunar valves. The ejection sound accompanying pulmonic valve disease decreases in intensity with inspiration, the only right-sided cardiac event to behave in this manner. Ejection sounds disappear as the culprit valve loses its pliability over time. They often are better

heard at the lower left sternal border than at the base of the heart. Nonejection clicks, which occur after the upstroke of the carotid pulse, are related to MVP. A systolic murmur may or may not follow. With standing, ventricular preload and afterload decrease and the click (and murmur) move closer to S_1 . With squatting, ventricular preload and afterload increase, the prolapsing mitral valve tenses later in systole, and the click (and murmur) move away from S_1 (**Fig. 11-7**).

Diastolic Sounds

The high-pitched opening snap (OS) of mitral stenosis occurs a short distance after S_2 ; the A_2 -OS interval is inversely proportional to the height of the left atrial (LA)-LV diastolic pressure gradient. The intensity of both S_1 and OS decreases with progressive calcification and rigidity of the anterior mitral leaflet. A pericardial knock (PK) is a high-pitched early diastolic sound, which corresponds in timing to the abrupt cessation of ventricular expansion after AV valve opening and to the prominent y descent seen in the jugular venous waveform in patients with constrictive pericarditis.^{26,27} A tumor "plop" rarely is heard with atrial myxoma; it is a low-pitched sound sometimes only heard in certain positions that arises from the diastolic prolapse of the tumor across the mitral valve. A diastolic murmur may be present, although most myxomas cause no sound. A third heart sound (S_3) occurs during the rapid filling phase of ventricular diastole. An S_3 may be normally present in children, adolescents, and young adults, but indicates systolic heart failure in older adults and carries important prognostic weight. A left-sided S_3 is a low-pitched sound best heard over the LV apex with the patient in the left lateral decubitus position, whereas a right-sided S_3 is usually heard at the lower left sternal border or in the subxiphoid position with the patient supine and may become louder with inspiration. A fourth heart sound (S_4) occurs during the atrial filling phase of ventricular diastole and is thought to

FIGURE 11-7 Behavior of the nonejection click (C) and systolic murmur of MVP. With standing, venous return decreases, the heart becomes smaller, and prolapse occurs earlier in systole. The click and murmur move closer to S_1 . With squatting, venous return increases, causing an increase in left ventricular chamber size. The click and murmur occur later in systole and move away from S_1 . (From Shaver JA, Leonard JJ, Leon DF. *Examination of the Heart. Part IV: Auscultation of the Heart*. Dallas, American Heart Association, 1990, p 13. Copyright 1990, American Heart Association.)

indicate presystolic ventricular expansion. An S_4 is especially common in patients with accentuated atrial contribution to ventricular filling (e.g., LV hypertrophy).

Cardiac Murmurs

Heart murmurs result from audible vibrations caused by increased turbulence and are defined by their timing within the cardiac cycle (Table 11-5; Fig. 11-8; see also Fig. 11-7) (and see also Chapter 63). Not all murmurs indicate valvular or structural heart disease. The accurate identification of a functional (benign) systolic murmur can obviate the need for echocardiography in many healthy subjects. The magnitude, dynamic change, and duration of the pressure difference between two cardiac chambers, or between the ventricles and their respective great arteries, dictate the duration, frequency, configuration, and intensity of murmurs. Intensity is graded on a scale of 1 to 6; a palpable thrill characterizes murmurs of grade 4 or higher intensity. Other important attributes that aid in identification include location, radiation, and response to bedside maneuvers, including quiet respiration.

Systolic Murmurs

Systolic murmurs are early, midsystolic, late, or holosystolic in timing. Acute severe MR results in a decrescendo, early systolic murmur because of the steep rise in pressure within the noncompliant left atrium (Fig. 11-9). Severe MR associated with posterior mitral leaflet prolapse or flail radiates anteriorly and to the base; MR caused by anterior leaflet involvement radiates posteriorly and to the axilla. With acute TR in patients with normal pulmonary artery pressures, an early systolic murmur, which increases in intensity with inspiration, may be audible at the lower left sternal border, and regurgitant *cv* waves may be visible in the jugular venous pulse. Midsystolic murmurs begin after S_1 and end before S_2 ; they usually are crescendo-decrescendo in configuration. Aortic stenosis or sclerosis causes

most midsystolic murmurs in adults. Accurate characterization of the severity of aortic stenosis at the bedside depends on cardiac output, stiffness of the carotid arteries, and associated findings. Other causes of a midsystolic heart murmur include HOCM, pulmonic stenosis, and increased pulmonary blood flow in patients with a large ASD and a left-to-right shunt. An isolated grade 1 or 2 midsystolic murmur in the absence of symptoms or other signs of heart disease is a benign finding that does not warrant further evaluation, including echocardiography. A late, apical systolic murmur usually indicates MVP; one or more nonejection clicks may be present. A similar murmur may be heard transiently during an episode of acute myocardial ischemia. In this setting, the MR is due to apical tethering and mal-coaptation of the leaflets in response to structural and functional changes of the ventricle and mitral annulus. The intensity of the murmur will vary with LV afterload. Holosystolic murmurs, which are plateau in configuration, derive from the continuous and wide pressure gradient between two cardiac chambers—the left ventricle and left atrium with chronic MR, the right ventricle and right atrium with chronic TR, and the left ventricle and right ventricle with membranous ventricular septal defect (VSD) without pulmonary hypertension. MR is best heard over the cardiac apex, TR at the lower left sternal border, and a VSD murmur at the mid-left sternal border, where a thrill is palpable in most patients. TR most commonly is secondary to annular dilation from RV enlargement with papillary muscle displacement and failure of tricuspid leaflet coaptation. Pulmonary artery hypertension also may be present.

Diastolic Murmurs

Diastolic murmurs invariably signify cardiac disease. Chronic AR causes a high-pitched decrescendo early to mid-diastolic murmur. With primary aortic valve disease, the murmur is best heard along the left sternal border, whereas with root enlargement and secondary AR, the murmur may radiate along the right sternal border. A midsystolic murmur caused by augmented and accelerated blood flow is also present with moderate to severe AR, and need not signify valve or outflow tract obstruction. The diastolic murmur is both softer and of shorter duration in acute AR, as a result of the rapid rise in LV diastolic pressure and the diminution of the aortic-LV diastolic pressure gradient. Additional features of acute AR include tachycardia, a soft S_1 , and the absence of peripheral findings of significant diastolic run-off. The murmur of pulmonic regurgitation (PR) is heard along the left sternal border and most often is due to annular enlargement from chronic pulmonary artery hypertension (Graham Steell murmur). Signs of RV pressure overload are present. PR also can occur with a congenitally deformed valve and is invariably present after repair of tetralogy of Fallot. In these settings, the murmur is relatively softer and lower-pitched. The severity of PR after surgical repair can be underappreciated. Mitral stenosis is the classic cause of a mid- to late diastolic murmur (see Fig. 11-8A, F). The stenosis also may be “silent”—for example, in patients with low cardiac output or large body habitus. The murmur is best heard over the apex with the patient in the left lateral decubitus position, is low-pitched (rumbling), and is introduced by an OS in the early stages of the disease. Presystolic accentuation (an increase in the intensity of the murmur in late diastole following atrial contraction) occurs in patients in sinus rhythm. Left-sided events usually obscure findings in patients with rheumatic tricuspid stenosis. Functional mitral stenosis or tricuspid stenosis refers to mid-diastolic murmurs created by increased, accelerated transvalvular flow, without valvular obstruction, in the setting of severe MR or TR, respectively, or ASD with a large left-to-right shunt. The low-pitched mid- to late apical diastolic murmur sometimes associated with AR (Austin Flint murmur) can be distinguished from mitral stenosis on the basis of its response to vasodilators and the presence of associated findings. Less common causes of a mid-diastolic murmur include atrial myxoma, complete heart block, and acute rheumatic mitral valvulitis (Carey Coombs murmur).

Continuous Murmurs

The presence of a continuous murmur implies a pressure gradient between two chambers or vessels during both systole and diastole.

TABLE 11-5 Principal Causes of Heart Murmurs

Systolic Murmurs	Mid-diastolic
Early Systolic	Mitral Mitral stenosis Carey Coombs murmur (mid-diastolic apical murmur in acute rheumatic fever) Increased flow across nonstenotic mitral valve (e.g., MR, VSD, PDA, high-output states, complete heart block)
Mitral—acute MR VSD Muscular Nonrestrictive with pulmonary hypertension Tricuspid—TR with normal pulmonary artery pressure	Tricuspid Tricuspid stenosis Increased flow across nonstenotic tricuspid valve (e.g., TR, ASD, anomalous pulmonary venous return) Left and right atrial tumors (myxoma) Severe or eccentric AR (Austin Flint murmur)
Midsystolic	Late Diastolic
Aortic Obstructive Supravalvular—supravalvular aortic stenosis, coarctation of the aorta Valvular—aortic stenosis and sclerosis Subvalvular—discrete, tunnel, or HOCM Increased flow, hyperkinetic states, AR, complete heart block Dilation of ascending aorta, atheroma, aortitis	Presystolic accentuation of mitral stenosis murmur Austin Flint murmur of severe or eccentric AR
Pulmonary Obstructive Supravalvular—pulmonary artery stenosis Valvular—pulmonic valve stenosis Subvalvular—infundibular stenosis (dynamic) Increased flow, hyperkinetic states, left-to-right shunt (e.g., ASD) Dilation of pulmonary artery	Continuous Murmurs
Late Systolic	PDA Coronary arteriovenous fistula Ruptured sinus of Valsalva aneurysm Aortic septal defect Cervical venous hum Anomalous left coronary artery Proximal coronary artery stenosis Mammary souffle of pregnancy Pulmonary artery branch stenosis Bronchial collateral circulation Small (restrictive) ASD with mitral stenosis Intercoastal arteriovenous fistula
Mitral—MVP, acute myocardial ischemia Tricuspid—tricuspid valve prolapse	
Holosystolic	
Atrioventricular valve regurgitation (MR, TR) Left-to-right shunt at ventricular level (VSD)	
Diastolic Murmurs	
Early Diastolic	
Aortic regurgitation Valvular—congenital (bicuspid valve), rheumatic deformity, endocarditis, prolapse, trauma, postvalvulotomy Dilation of valve annulus—aortic dissection, annuloaortic ectasia, cystic medial degeneration, hypertension, ankylosing spondylitis Widening of commissures—syphilis Pulmonic regurgitation Valvular—postvalvulotomy, endocarditis, rheumatic fever, carcinoid Dilation of valve annulus—pulmonary hypertension; Marfan syndrome Congenital—isolated or associated with tetralogy of Fallot, VSD, pulmonic stenosis

Philadelphia, Saunders, 2005, pp 77-106; and Norton PJ, O'Rourke RA: *Approach to the patient with a heart murmur*. In Braunwald E, Goldman L (eds): *Primary Cardiology*. 2nd ed. Philadelphia, Elsevier, 2003, pp 151-168.

FIGURE 11-8 Diagram of principal heart murmurs. **A**, Presystolic accentuation of the murmur of mitral stenosis with sinus rhythm. **B**, Holosystolic murmur of chronic, severe MR or TR, or VSD without severe pulmonary hypertension. **C**, Ejection sound and crescendo-decrescendo murmur of bicuspid aortic stenosis. **D**, Ejection sound and crescendo-decrescendo murmur that extends to P₂ in bicuspid pulmonic stenosis. **E**, Early decrescendo diastolic murmur of AR or PR. **F**, Opening snap (OS) and mid-diastolic rumble of mitral stenosis. **G**, Diastolic filling sound (S₃) and mid-diastolic murmur associated with severe MR, TR, or ASD with significant left-to-right shunt. **H**, Continuous murmur of PDA that envelops S₂. (Modified from Wood P: *Diseases of the Heart and Circulation*. Philadelphia, Lippincott, 1968; and O'Rourke RA, Braunwald E: *Physical examination of the cardiovascular system*. In Kasper D, Braunwald E, Fauci A, et al [eds]: *Harrison's Principles of Internal Medicine*. 16th ed. New York, McGraw-Hill, 2005, p 1309.)

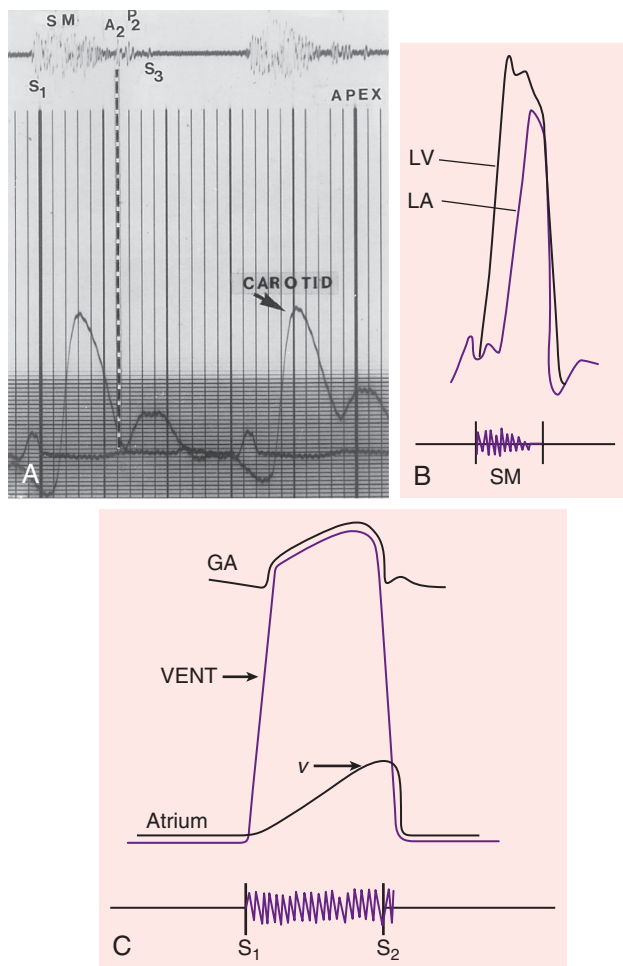

FIGURE 11-9 **A**, Phonocardiogram (top) obtained in a patient with acute severe MR showing a decrescendo early systolic murmur and diastolic filling sound (S_3). **B**, LV and left atrial (LA) pressure waveforms demonstrating the abrupt rise in LA pressure and attenuation of the LV-LA pressure gradient, resulting in the duration and configuration of the murmur. **C**, Illustration of great artery (GA) and ventricular (VENT) and atrial pressures with corresponding phonocardiogram in chronic MR or TR. Note the holosystolic timing and plateau configuration of the murmur, both of which derive from the large ventricular-atrial pressure gradient throughout systole. SM = systolic murmur; v = v wave. (From Braunwald E, Perloff JK: *Physical examination of the heart and circulation*. In Zipes D, Libby P, Bonow RO, Braunwald E [eds]: *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 7th ed. Philadelphia, Saunders, 2005, p 97.)

These murmurs begin in systole, peak near S_2 , and continue into diastole. They can be difficult to distinguish from systolic and diastolic murmurs in patients with mixed aortic or pulmonic valve disease. Examples are the murmurs associated with PDA, ruptured sinus of Valsalva aneurysm, and coronary, great vessel, or hemodialysis-related arteriovenous fistulas. The cervical venous hum and mammary souffle of pregnancy are two benign variants.

Dynamic Auscultation

Simple bedside maneuvers can help identify heart murmurs and characterize their significance (Table 11-6). Right-sided events, except for the pulmonic ejection sound, increase with inspiration and decrease with expiration; left-sided events behave oppositely (100% sensitivity, 88% specificity). The intensity of the murmurs associated with MR, VSD, and AR will increase in response to maneuvers that increase LV afterload (e.g., handgrip, vasopressor administration) and decrease after exposure to vasodilating agents (e.g., amyl nitrite). The response of the murmur associated with MVP to standing and squatting has previously been described. The murmur of HOCM behaves in a directionally similar manner, becoming softer and shorter with squatting (95% sensitivity, 85% specificity) and longer

TABLE 11-6 Interventions for Altering Intensity of Cardiac Murmurs

Respiration: Right-sided murmurs generally increase with inspiration. Left-sided murmurs usually are louder during expiration.

Valsalva maneuver: Most murmurs decrease in length and intensity. Two exceptions are the systolic murmur of HOCM, which usually becomes much louder, and that of MVP, which becomes longer and often louder. After release of the Valsalva maneuver, right-sided murmurs tend to return to baseline intensity earlier than left-sided murmurs.

Exercise: Murmurs caused by blood flow across normal or obstructed valves (as in pulmonic and mitral stenosis) become louder with both isotonic and isometric (handgrip) exercise. Murmurs of MR, VSD, and AR also increase with handgrip exercise.

Positional changes: With standing, most murmurs diminish; two exceptions are the murmur of HOCM, which becomes louder, and that of MVP, which lengthens and often is intensified. With squatting, most murmurs become louder, but those of HOCM and MVP usually soften and may disappear. Passive leg raising usually produces the same results as squatting.

Post-ventricular premature beat or AF: Murmurs originating at normal or stenotic semilunar valves increase in intensity during the cardiac cycle after a ventricular premature beat or in the beat after a long cycle length in AF. By contrast, systolic murmurs caused by AV valve regurgitation do not change, diminish (papillary muscle dysfunction), or become shorter after a premature beat (MVP).

Pharmacologic interventions: During the initial relative hypotension after amyl nitrite inhalation, murmurs of MR, VSD, and AR decrease in intensity, whereas the murmur of AS increases in intensity because of increased stroke volume. During the later tachycardia phase, murmurs of mitral stenosis and right-sided lesions also become louder. This intervention may help distinguish the murmur of the Austin Flint phenomenon from that of mitral stenosis. The response in MVP often is biphasic (softer and then louder than control).

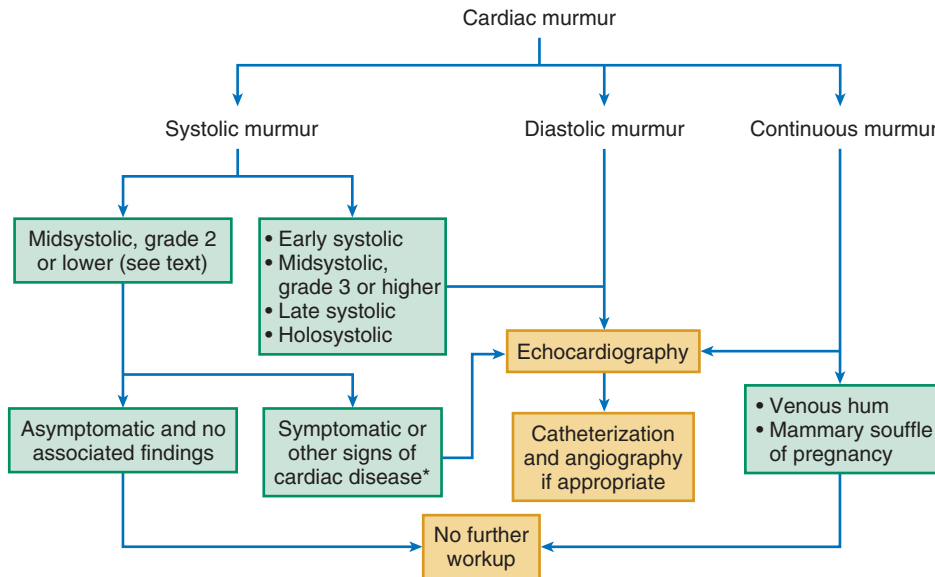

Transient arterial occlusion: Transient external compression of both brachial arteries by bilateral cuff inflation to 20 mm Hg greater than peak systolic pressure augments the murmurs of MR, VSD, and AR, but not murmurs from other causes.

From Bonow RO, Carabello BA, Chatterjee K, et al: ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 1998 Guidelines for the Management of Patients with Valvular Heart Disease) developed in collaboration with the Society of Cardiovascular Anesthesiologists endorsed by the Society for Cardiovascular Angiography and Interventions and the Society of Thoracic Surgeons. *J Am Coll Cardiol* 48:e18, 2006.

and louder on rapid standing (95% sensitivity, 84% specificity). The intensity of the murmur of HOCM also increases with the Valsalva maneuver (65% sensitivity, 95% specificity). A change in the intensity of a systolic murmur in the first beat after a premature beat, or in the beat after a long cycle length in patients with AF, suggests aortic stenosis rather than MR, particularly in an older patient, in whom the murmur of aortic stenosis is well transmitted to the apex (Gallavardin effect). Systolic murmurs that are due to LV outflow obstruction, including those caused by aortic stenosis, will increase in intensity in the beat following a premature beat because of the combined effects of enhanced LV filling and post-extrasystolic potentiation of contractile function. Forward flow accelerates, causing an increase in the gradient and a louder murmur. The intensity of the murmur of MR does not change in the post-premature beat, because relatively little further increase occurs in mitral valve flow or change in the LV-LA gradient.

Indications for Echocardiography

Patients with a midsystolic murmur of grade 2 intensity or less, who lack symptoms and have no other signs of cardiovascular disease, or those with benign continuous murmurs, do not require transthoracic echocardiography (TTE)²⁸ (Fig. 11-10). Other patients should undergo echocardiographic study to characterize cardiac structure and function and to estimate pulmonary artery pressures.

*If an electrocardiogram or chest x-ray has been obtained and is abnormal, echocardiography is indicated.

INTEGRATED, EVIDENCE-BASED APPROACH TO SPECIFIC CARDIAC DISORDERS

Heart Failure

History

Both exertional and resting symptoms should be investigated. Common signs and symptoms include dyspnea, fatigue, exercise limitation, orthopnea, and edema. In a review of 22 studies of adult patients presenting to an emergency department with dyspnea, the probability of heart failure was best predicted by a past history of heart failure (LR, 5.8; 95% CI, 4.1 to 8.0), paroxysmal nocturnal dyspnea (LR, 2.6; 95% CI, 1.5 to 4.5), a third heart sound (LR, 11; 95% CI, 4.9 to 25), or AF (LR, 3.8; 95% CI, 1.7 to 8.8).²⁹ An initial clinical impression of heart failure as noted by a physician was one of the stronger clinical predictors of this diagnosis (LR, 4.4; 95% CI, 1.8 to 10.0). With the exception of paroxysmal nocturnal dyspnea, these same features also predicted heart failure when there was concomitant pulmonary disease. The addition of testing for N-terminal pro-B-type natriuretic peptide (NT-pro-BNP) increases diagnostic accuracy only modestly (c-statistic, 0.83 versus 0.86).⁸

Severe and sudden onset dyspnea indicates acute pulmonary edema, typically precipitated by ischemia, arrhythmia, sudden left-sided valvular regurgitation, and/or accelerated hypertension. It is important to exclude other causes such as pulmonary embolism and pneumothorax. The extent of limitation also should be defined because functional capacity, as assessed by NYHA classification, strongly and independently predicts the risk of death for patients with heart failure. Self-reported functional capacity and objectively measured cardiovascular performance can differ substantially. Symptoms that occur at rest may have greater predictive value for the diagnosis of heart failure than that of exertional symptoms. Orthopnea is not specific for heart failure and can occur in patients with severe ascites or emphysema. Trepopnea, which is dyspnea or discomfort experienced in the lateral decubitus position, also may be present. Patients with heart failure prefer sleeping on their right side, and trepopnea probably accounts for the predominance of right-sided pleural effusions in this population. Paroxysmal nocturnal dyspnea also is

common in patients with heart failure. Cheyne-Stokes respirations may be apparent when the patient is awake.¹⁶ The prevalence of central sleep apnea or Cheyne-Stokes respirations ranges from 20% to 62% in various heart failure studies,³⁰ and either of these disorders portends an increased mortality risk. Lower-extremity edema is usually pitting and becomes more prominent as the day progresses for the ambulatory patient. Clinically evident edema probably indicates volume excess. In patients with advanced right-sided heart failure, uncomfortable hepatomegaly and ascites may predominate. Patients with chronic heart failure often lack pulmonary rales or lower extremity edema.

Few studies have explored the predictive values of various signs and symptoms of heart failure. In a systematic review,³¹ orthopnea only modestly predicted increased filling pressures. Dyspnea and edema were similarly useful, but were most predictive when combined with physical examination findings (S_3 , tachycardia, elevated JVP, low pulse pressure, rales, abdominojugular reflex). When combined with other findings, a total of three or more symptoms or signs predicted a greater than 90% likelihood of increased filling pressures if severe LV dysfunction was not known. By contrast, if one or no findings or symptoms were present, the likelihood of increased filling pressures was less than 10%. The commonly used Framingham criteria for heart failure diagnosis in patients with reduced ejection fraction has only modest specificity (63%) and sensitivity (63%).

The distinction between heart failure with reduced ejection fraction, and that with preserved ejection fraction, can be made at the bedside with modest accuracy. Systolic function is more likely to be preserved when patients are female or older and have an increased BMI, but such findings lack adequate specificity or sensitivity to guide therapy. Furthermore, diastolic dysfunction does not exclude systolic dysfunction.

Physical Examination

In most patients with heart failure who require hospitalization, the reason for admission is volume overload; failure to relieve it has negative prognostic impact. Four signs are commonly used to predict elevated filling pressures: jugular venous distention/abdominojugular reflex, presence of an S_3 and/or S_4 , rales, and pedal edema. In general, the use of a combination of findings, rather than relying on isolated clinical findings, improves diagnostic accuracy. Some clinicians advocate assessment of the patient with heart failure along two basic axes—volume status (“dry” or “wet”) and perfusion status (“warm” or “cold”)—as a useful guide to therapy (see Figure 23-2). This approach has prognostic usefulness, particularly in assessing patients at discharge after admission for heart failure. For example, such patients discharged with a “wet” or “cold” profile experience worse outcomes (HR, 1.5; 95% CI, 1.1 to 2.1; $P = 0.017$) compared with those discharged “warm and dry” (HR 0.9; 95% CI, 0.7 to 2.1; $P = 0.5$).²³ Advanced training may be required to achieve this level of diagnostic precision with the physical examination.³²

Jugular Venous Pressure

The JVP provides the readiest bedside estimate of LV filling pressure. In the Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE) trial, 82% of patients whose estimated right atrial pressure was higher than 8 mm Hg (10.5 cm H_2O) had a measured right atrial pressure higher than

8 mm Hg. The same investigators also identified 9 of the 11 patients with pressures lower than 8 mm Hg.²³ Although the JVP estimates RV filling pressure, it has a predictable relationship with pulmonary artery wedge pressure. Drazner and colleagues³³ found that the right atrial pressure reliably predicted the pulmonary artery wedge pressure; the positive predictive value of a right atrial pressure higher than 10 mm Hg for a pulmonary artery wedge pressure higher than 22 mm Hg was 88%. In addition, the pulmonary artery systolic pressure could be estimated as twice the wedge pressure. In the ESCAPE trial, an estimated right atrial pressure higher than 12 mm Hg and two-pillow orthopnea were the only bedside parameters that provided incremental value to the prediction of a pulmonary artery wedge pressure higher than 22 mm Hg, and compared favorably with BNP levels.²³ Echocardiography and BNP determinations may not always provide incremental value to the clinical assessment of heart failure by experienced observers.³⁴

An elevated JVP has prognostic significance. Drazner and associates³⁵ demonstrated that the presence of jugular vein distention, at the time of enrollment in a large clinical heart failure trial (11% of the Studies of Left Ventricular Dysfunction [SOLVD] treatment study participants), after adjustment for other markers of disease severity, predicted heart failure hospitalizations (relative risk [RR], 1.32; 95% CI, 1.08 to 1.62), death from pump failure (RR, 1.37; 95% CI, 1.07 to 1.75), and death plus heart failure hospitalization (RR, 1.30; 95% CI, 1.11 to 1.53) (Fig. 11-11). The investigators extended these observations to asymptomatic subjects enrolled in the SOLVD prevention study, among whom jugular vein distention was less common (1.7% of the

study population).³⁶ In patients presenting with dyspnea, the abdominojugular reflex is useful in predicting heart failure (LR, 6.0; 95% CI, 0.8 to 51) and suggests a pulmonary artery wedge pressure higher than 15 mm Hg (LR, 6.7; 95% CI, 3.3 to 13.4).¹⁹ The presence of jugular vein distention, either at rest or induced, had the best combination of sensitivity (81%), specificity (80%), and predictive accuracy (81%) for elevation of the pulmonary artery wedge pressure.

Third and Fourth Heart Sounds

The third heart sound (S_3) predicts ejection fraction poorly because it reflects primarily diastolic rather than systolic performance. In patients with heart failure, an S_3 is equally prevalent in those with and without LV systolic dysfunction. A rigorous assessment of the S_3 was conducted by Marcus and colleagues in 100 patients with various cardiovascular conditions undergoing elective cardiac catheterization.^{37,38} Cardiology fellows ($n = 18$; K statistic, 0.37; $P < 0.001$) and faculty ($n = 26$; K statistic, 0.29; $P = 0.003$) performed better than residents ($n = 102$; no significant agreement) in the identification of a phonocardiographically confirmed S_3 . Furthermore, an S_3 predicted an increase in both LV end-diastolic pressure (LVEDP) (greater than 15 mm Hg) and BNP (greater than 100 pg/mL) and depressed ventricular systolic function (ejection fraction less than 0.50), although sensitivities were low (32% to 52%) (Fig. 11-12). An S_4 had comparable sensitivity (40% to 46%) but inferior specificity (72% to 80% for an S_4 versus 87% to 92% for an S_3) (Table 11-7). A third heart sound frequently may be heard in patients referred for transplant evaluation, but predicts poorly elevated filling pressures. Alternatively, the lack

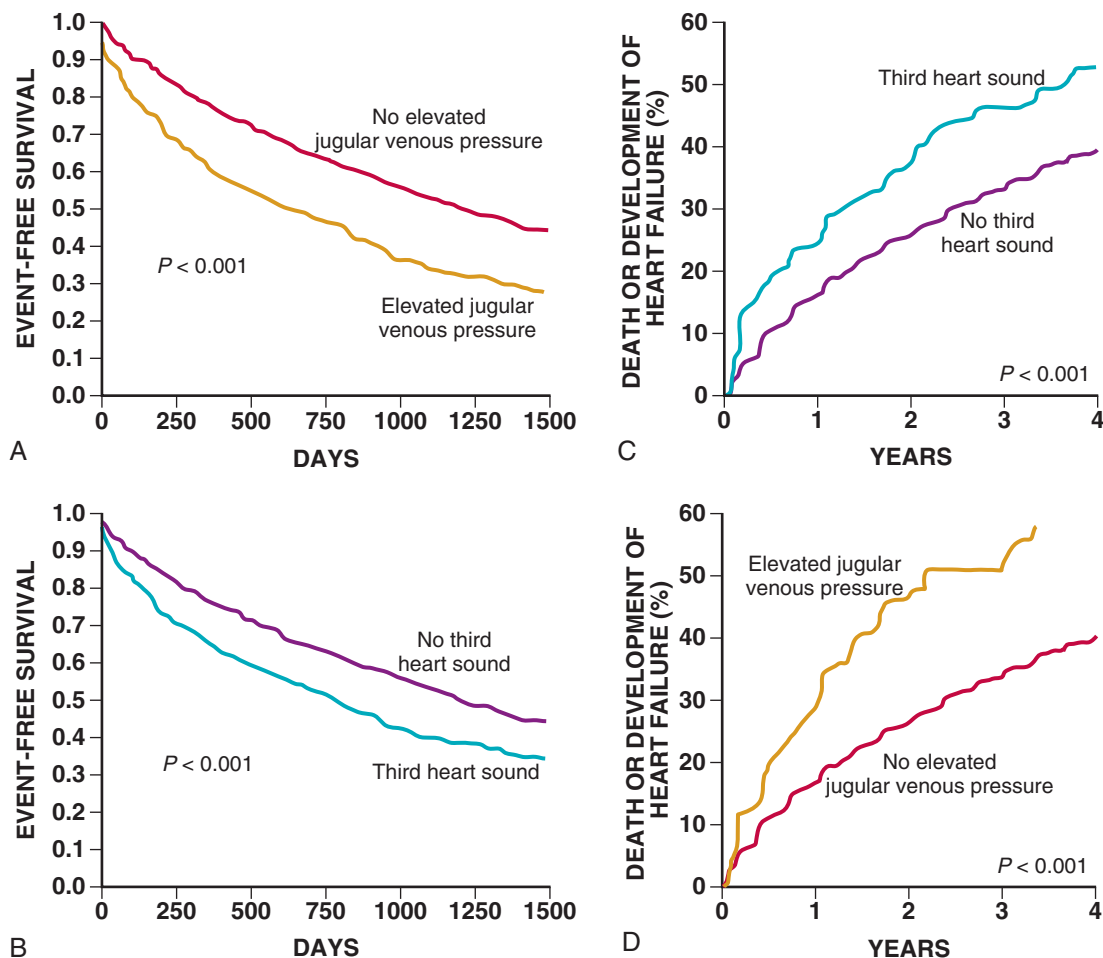

FIGURE 11-11 Kaplan-Meier plots demonstrating prognostic value of an elevated jugular venous pressure and third heart sound (S_3) in symptomatic (A and B) and asymptomatic (C and D) patients with heart failure who also had systolic dysfunction. (A, B, From Drazner MH, Rame JE, Stevenson LW, Dries DL: Prognostic importance of elevated jugular venous pressure and a third heart sound in patients with heart failure. *N Engl J Med* 345:574, 2001; C, D, from Drazner MH, Rame JE, Dries DL: Third heart sound and elevated jugular venous pressure as markers of the subsequent development of heart failure in patients with asymptomatic left ventricular dysfunction. *Am J Med* 114:431, 2003.)

FIGURE 11-12 Median LVEDP (A) and LV ejection fraction (LVEF) (B) in patients in whom the phonocardiographic tracing demonstrated the presence of a third and/or fourth heart sound. Median and interquartile ranges, error bars, and outlier values (circles) are shown; P values are compared with data in the first column. (From Marcus GM, Gerber IL, McKeown BH, et al: Association between phonocardiographic third and fourth heart sounds and objective measures of left ventricular function. *JAMA* 293:2238, 2005.)

of an S₃ cannot exclude a diagnosis of heart failure, but its presence reliably indicates ventricular dysfunction.

The prognostic value of an S₃ in chronic heart failure was established in the SOLVD treatment and prevention studies.^{33,35,36} The investigators found that an S₃ predicted cardiovascular morbidity and mortality (see Fig. 11-11). The relative risk for heart failure hospitalization and death in patients with an S₃ was of comparable magnitude in the prevention and treatment cohorts. These observations remained significant after adjustment for markers of disease severity, and were even more powerful when combined with the presence of an elevated JVP. An S₃ also predicts a higher risk of adverse outcomes in other settings, such as that of MI or noncardiac surgery.

Rales and Edema

In older studies of patients with chronic heart failure, approximately 75% to 80% of participants lacked rales despite elevated pulmonary artery wedge pressures, presumably because of enhanced lymphatic drainage. The chest radiograph similarly lacked sensitivity for increased filling pressures in these studies. Pedal edema is neither sensitive nor specific for the diagnosis of heart failure and has low predictive value as an isolated variable.

Valsalva Maneuver

The blood pressure response to the Valsalva maneuver can be measured noninvasively using a blood pressure cuff or commercially available devices. The Valsalva maneuver consists of four phases (Fig. 11-13). In a normal response, Korotkoff sounds are audible only

TABLE 11-7 Test Characteristics in Computerized Detection of Heart Sounds*

CHARACTERISTIC	LVEDP > 15 mm Hg (%)	LVEF < 50% (%)	BNP > 100 pg/ mL (%)

*Data are presented as percents (with 95% CI).

Modified from Marcus GM, Gerber IL, McKeown BH, et al: Association between phonocardiographic third and fourth heart sounds and objective measures of left ventricular function. *JAMA* 293:2238, 2005.

during phases I and IV, because the systolic pressure normally rises at the onset and release of the strain phase. Two abnormal responses to the Valsalva maneuver in heart failure are recognized: (1) absence of the phase IV overshoot and (2) the square-wave response (Fig. 11-14). The absent overshoot pattern indicates decreased systolic function; the square-wave response indicates elevated filling pressures and appears to be independent of ejection fraction.³⁹ The responses can be quantified using the pulse amplitude ratio if the pulse pressure is measured during the maneuver. This ratio compares the minimum pulse pressure at the end of the strain phase against the maximum pulse pressure at the onset of the strain phase; a higher ratio is consistent with a square-wave response.

Other Findings

In the absence of hypertension, the pulse pressure is determined by the stroke volume and vascular stiffness, and can be used to assess cardiac output. In a cohort of patients with chronic systolic heart failure, the proportional pulse pressure ([systolic – diastolic]/systolic) correlated well with cardiac index (correlation coefficient [*r*] = 0.82; *P* < 0.001), stroke volume index (*r* = 0.78; *P* < 0.001), and the inverse of systemic vascular resistance (*r* = 0.65; *P* < 0.001). Using a proportional pulse pressure of 25%, the cardiac index could be predicted: if the value was lower than 25%, the cardiac index was less than 2.2 L/min/m² in 91% of patients; if the value was higher than 25%, the cardiac index was higher than 2.2 L/min/m² in 83% of patients.⁴⁰ The best assessment for systemic perfusion and cardiac index, however, appears to be overall clinical impression, the so-called “cold” profile (see Figure 23-2). The gestalt of specialized heart failure clinicians performed better than proportional pulse pressure, systolic blood pressure, cool extremities, or fatigue in predicting an invasively measured cardiac index lower than 2.3 L/min/m².²³ This prediction rule has not been reported in other patient groups, in larger

FIGURE 11-13 The normal Valsalva response. (From Nishimura RA, Tajik AJ: *The Valsalva maneuver—3 centuries later*. *Mayo Clin Proc* 79:577, 2004.)

Phase I: Increase in systolic pressure with initial strain due to increase in intrathoracic pressure

Phase II: Decrease in stroke volume and pulse pressure and reflex tachycardia with continued strain due to decrease in venous return and increase in vascular resistance

Phase III: Brief, sudden decrease in systolic pressure due to sudden decrease in intrathoracic pressure

Phase IV: Overshoot of systolic pressure and reflex bradycardia due to increased venous return and decreased systemic vascular resistance

tactile vocal fremitus makes a pleural effusion less likely (negative LR, 0.21; 95% CI, 0.12 to 0.37).³¹

Valvular Heart Disease

A careful history and physical examination can reveal much regarding lesion severity, natural history, indications for surgery, and outcomes in patients with valvular heart disease (see also Chapter 63). The history in patients with known or suspected valvular heart disease should rely on the use of a functional classification scheme (see Table 11-1). Onset of even mild functional limitation is an indication for mechanical (surgical) correction of the responsible valve lesion. Valvular heart disease most often is first suspected because of a heart murmur. Cardiologists can detect systolic heart murmurs with fair reliability (interobserver kappa coefficient, 0.30 to 0.48), and usually can confirm or rule out aortic stenosis, HOCM, MR, MVP, TR, and functional murmurs. The use of handheld ultrasound devices may improve detection and accuracy rates.⁴¹⁻⁴³

Mitral Stenosis

In patients with mitral stenosis, survival declines following symptom onset and worsens with increasing degrees of functional limitation (NYHA class) and as pulmonary hypertension increases. Findings on physical examination vary with the chronicity of the disease, heart rate, rhythm, and cardiac output. It can be difficult to estimate the severity of the valve lesion in older patients with less pliable valves, rapid AF, or low cardiac output. Severe mitral stenosis is suggested by (1) a long or holodiastolic murmur, indicating a persistent LA-LV gradient, (2) a short A₂-OS interval, consistent with higher LA pressure, (3) a loud P₂ (or single S₂) and/or an RV lift, suggestive of pulmonary hypertension, and (4) elevated JVP with *cv* waves, hepatomegaly, and lower extremity edema—all signs of right heart failure. Neither the intensity of the diastolic murmur nor the presence of

presystolic accentuation in patients with sinus rhythm accurately reflects lesion severity.

Mitral Regurgitation

The symptoms associated with MR depend on its severity and time course of development. Acute severe MR that occurs with papillary muscle rupture or infective endocarditis usually results in sudden

FIGURE 11-14 Abnormal Valsalva responses assessed using the pattern of Korotkoff sounds. **A**, Normal, sinusoidal response with sounds intermittent during strain and release. **B**, Briefly audible sounds during initial strain phase suggests only impaired systolic function in absence of fluid overload. **C**, Persistence of Korotkoff sounds throughout strain phase suggests elevated left ventricular filling pressures. BP = blood pressure. (From Shamsham F, Mitchell J: *Essentials of the diagnosis of heart failure*. *Am Fam Physician* 61:1319, 2000.)

cohorts, or in more contemporary studies. Pleural effusions also are common in patients with heart failure, in whom they typically are right-sided, as noted previously. Dullness to percussion is the simplest finding to elicit in identifying a pleural effusion and is superior (LR, 8.7; 95% CI, 2.2 to 33.8) to auscultatory percussion, decreased breath sounds, asymmetric chest expansion, increased vocal resonance, crackles, or pleural friction rubs. By contrast, absence of reduced

and profound dyspnea from pulmonary edema. Examination findings may be misleading because the LV impulse usually is neither enlarged nor displaced, and the systolic murmur is early in timing and decrescendo in configuration (see Fig. 11-9). The murmur also may be louder at the lower left sternal border or in the axilla than at the apex. A new systolic murmur developing early after an MI may not be audible in a ventilated or obese patient.

Several findings suggest chronic severe MR: (1) an enlarged, displaced, but dynamic LV apex beat; (2) an apical systolic thrill (murmur intensity of grade 4 or greater); (3) a mid-diastolic filling complex comprising an S_3 and a short, low-pitched murmur, indicative of accelerated and enhanced diastolic mitral inflow; (4) wide but physiologic splitting of S_2 caused by early aortic valve closure; and (5) a loud P_2 or RV lift. The findings in patients with MVP can vary, depending on LV loading conditions. The combination of a nonejection click and mid- to late systolic murmur predicts MVP best, as confirmed by TTE criteria (LR, 2.43).

Aortic Stenosis

A slowly rising carotid upstroke (*pulsus tardus*), reduced carotid pulse amplitude (*pulsus parvus*), reduced intensity of A_2 , and mid- to late peaking of the systolic murmur help gauge the severity of aortic stenosis. The intensity of the murmur depends on cardiac output and body size (peak momentum transfer) and does not reliably reflect stenosis severity. In a 35-year follow-up study of 2014 apparently healthy middle-aged Norwegian men, the presence of even a low-grade systolic murmur was associated with an almost fivefold increased age-adjusted risk for aortic valve replacement.⁴⁴ No single physical examination finding has both high sensitivity and high specificity for the diagnosis of severe aortic stenosis, and only a reduced carotid upstroke amplitude may independently predict outcome. Clinical experience has established the difficulty of assessing carotid upstroke characteristics in older patients, in patients with hypertension, and in low-output states. Distinguishing the murmur of hemodynamically significant aortic stenosis from that caused by lesser degrees of stenosis is also challenging. Even with aortic sclerosis, the murmur can be of grade 2 or 3 intensity, although it peaks in midsystole. The carotid upstroke should be normal, A_2 should be preserved, and the electrocardiogram (ECG) should lack evidence of LV hypertrophy. Nevertheless, TTE often is necessary to clarify this distinction, especially in older patients with hypertension. Signal analysis of digitally captured cardiovascular sounds using spectral display can distinguish the murmur of aortic sclerosis from a murmur resulting from hemodynamically significant aortic stenosis.⁹ The differential diagnosis of a systolic murmur related to LV outflow obstruction includes valvular aortic stenosis, HOCM, discrete membranous subaortic stenosis (DMSS), and supra-aortic stenosis (SVAS). The presence of an ejection sound indicates a valvular cause. HOCM can be distinguished on the basis of the response of the murmur to the Valsalva maneuver and standing or squatting. Patients with DMSS will commonly have a diastolic murmur indicative of AR but not an ejection sound, whereas in patients with SVAS, the right arm blood pressure is more than 10 mm Hg greater than the left arm blood pressure.

Aortic Regurgitation

Patients with acute severe AR present with pulmonary edema and symptoms and signs of low forward cardiac output. Tachycardia is invariably present; systolic blood pressure is not elevated, and the pulse pressure is not significantly widened. S_1 is soft because of premature closure of the mitral valve. The intensity and duration of the diastolic murmur are attenuated by the rapid rise in LV diastolic pressure and diminution of the aortic-LV diastolic pressure gradient. In patients with acute type A aortic dissection, the presence of a diastolic murmur (present in almost 30% of cases) does little to change the pretest probability of dissection. Acute severe AR is poorly tolerated and mandates emergency surgery. Typical symptoms associated with chronic, severe AR include dyspnea, fatigue, chest discomfort, and palpitations. A decrescendo diastolic blowing murmur suggests chronic AR. A midsystolic murmur indicative of augmented LV outflow is invariably heard at the base. Aortic stenosis may coexist.

The absence of a diastolic murmur significantly reduces the likelihood of moderate or greater AR (LR, 0.1), whereas the presence of a typical diastolic murmur increases the likelihood of moderate or greater AR (LR, 4.0 to 8.3). In addition, in patients with chronic AR, the intensity of the murmur correlates with the severity of the lesion. A grade 3 diastolic murmur has an LR of 4.5 (95% CI, 1.6 to 14.0) for distinguishing severe AR from mild or moderate AR.⁴⁵ Data regarding the significance of an Austin Flint murmur are conflicting. Little evidence supports the historical claims of the importance of almost all the eponymous peripheral signs of chronic AR, which number at least 12. The Hill sign (brachial-popliteal systolic blood pressure gradient higher than 20 mm Hg) may be the single exception (sensitivity of 89% for moderate to severe AR), although its supporting evidence base also is weak.

Tricuspid Valve Disease

Left-sided valve lesions often obscure the symptoms and signs of tricuspid stenosis. An elevated JVP together with a delayed y descent, abdominal ascites, and edema suggests severe tricuspid stenosis. Auscultatory findings are difficult to appreciate but mimic those in mitral stenosis and may worsen during inspiration. The symptoms of TR resemble those of tricuspid stenosis. Severe TR causes elevated JVP with prominent *cv* waves, a parasternal lift, pulsatile liver, ascites, and edema. The intensity of the holosystolic murmur of TR increases with inspiration (Carvallo sign). Murmur intensity does not accurately reflect the severity of the valve lesion. Primary and secondary causes of TR should be distinguished.

Pulmonic Valve Disease

Pulmonic stenosis may cause exertional fatigue, dyspnea, lightheadedness, and chest discomfort ("right ventricular angina"). Syncope denotes severe obstruction. The midsystolic murmur of pulmonic stenosis is best heard at the second left interspace. With severe pulmonic stenosis, the interval between S_1 and the pulmonic ejection sound narrows, and the murmur peaks in late systole and may extend beyond A_2 . P_2 becomes inaudible. Signs of significant RV pressure overload include a prominent jugular venous *a* wave and a parasternal lift. PR occurs most commonly as a secondary manifestation of significant pulmonary artery hypertension and annular dilation, but it may also reflect a primary valve disorder (e.g., congenital bicuspid valve) or develop as a complication of RV outflow tract surgery. Symptoms vary as a function of the severity of PA hypertension and the level of RV compensation. The diastolic murmur of secondary PR (Graham Steell) can be distinguished from that caused by AR on the basis of its increase in intensity with inspiration, its later onset (after A_2 and with P_2), and its slightly lower pitch. When a typical murmur is audible, the likelihood of PR increases (LR, 17), but the absence of a murmur does not exclude PR (LR, 0.9). With severe pulmonary artery hypertension and PR, P_2 is usually palpable and there are signs of RV pressure and volume overload on examination.

Prosthetic Heart Valves

The differential diagnosis of functional limitation after valve replacement surgery includes prosthetic valve dysfunction, arrhythmia, and impaired ventricular function. Prosthetic valve dysfunction can occur as a result of thrombosis, pannus ingrowth, infection, or structural deterioration. Symptoms and signs mimic those of native valve disease and may arise acutely or develop gradually. The first clue that prosthetic valve dysfunction may be present often is a *change* in the quality of the heart sounds or the appearance of a new murmur. The heart sounds with a bioprosthetic valve resemble those generated by native valves. A bioprosthesis in the mitral position usually is associated with a midsystolic murmur (from turbulence created by systolic flow across the valve struts that project into the LV outflow tract) and a soft, mid-diastolic murmur that occurs with normal LV filling. The diastolic murmur usually is heard only in the left lateral decubitus position at the apex. A high-pitched or holosystolic apical murmur signifies paravalvular or bioprosthetic regurgitation that requires echocardiographic verification and careful follow-up evaluation. Depending on the magnitude of the regurgitant volume, a diastolic

murmur may be audible. Clinical deterioration can occur rapidly after initial manifestation of bioprosthetic failure.

A bioprosthesis in the aortic position is invariably associated with a midsystolic murmur at the base of grade 3 or less intensity. A diastolic murmur of AR is abnormal under any circumstance and merits additional investigation. A decrease in the intensity of either the opening or closing sounds of a mechanical prosthesis, depending on its type, is a worrisome finding. A high-pitched apical systolic murmur in patients with a mechanical mitral prosthesis, or a decrescendo diastolic murmur in patients with a mechanical aortic prosthesis, indicates paravalvular regurgitation or prosthetic dysfunction. Patients with prosthetic valve thrombosis may present with signs of shock, muffled heart sounds, and soft murmurs.

Pericardial Disease

Pericarditis

The typical pain of acute pericarditis starts abruptly, is sharp, and varies with position. It can radiate to the trapezius ridge. Associated fever or history of a recent viral illness may provide additional clues. A pericardial friction rub is almost 100% specific for the diagnosis, although its sensitivity is not as high, because the rub may wax and wane over the course of an acute illness or may be difficult to elicit. This leathery or scratchy, typically two- or three-component sound also may be monophasic. It usually is necessary to auscultate the heart with the patient in several positions. The ECG may provide additional clues related to ST segment elevation and P-R segment depression. A transthoracic ECG is routinely obtained to assess the volume and appearance of any effusion and to look for early signs of hemodynamic compromise. (See Chapter 71 for a more complete discussion of pericardial disease.)

Pericardial Tamponade

Pericardial tamponade occurs when intrapericardial pressure equals or exceeds right atrial pressure. The time course of its development depends on the volume of the effusion, the rate at which it accumulates, and pericardial compliance. The most common associated symptom is dyspnea (sensitivity, 87% to 88%).⁴⁶ Hypotension (sensitivity, 26%) and muffled heart sounds (sensitivity, 28%) are relatively insensitive indicators of tamponade. A pulsus paradoxus greater than 12 mm Hg in a patient with a large pericardial effusion predicts tamponade with a sensitivity of 98%, a specificity of 83%, and a positive LR of 5.9 (95% CI, 2.4 to 14). Echocardiography is indicated in all patients with suspected pericardial tamponade.

Constrictive Pericarditis

Constrictive pericarditis is an uncommon clinical entity that occurs with previous chest irradiation, cardiac or mediastinal surgery, chronic tuberculosis, or malignancy. Dyspnea, fatigue, weight gain, abdominal bloating, and leg swelling dominate the clinical presentation. The diagnosis most often is first suspected after inspection of the JVP and waveforms, with elevation and inscription of the classic M or W contour caused by prominent x and y descents and a Kussmaul sign. Evidence of pleural effusions and ascites often can be found. On rare occasion, a PK is audible. Distinction from restrictive cardiomyopathy often is not possible on the basis of the history and physical examination alone.

FUTURE DIRECTIONS

The history and physical examination play an invaluable role in the initial assessment of the patient with known or suspected cardiovascular disease. Concerns regarding the escalating costs of medical care may reinforce the value of these time-honored traditions to guide appropriate use of imaging and invasive diagnosis modalities. These considerations should spur additional efforts to establish their accuracy and performance characteristics. Recognition of the need to reestablish the mentored patient evaluation as a dedicated component of training programs, along with mechanisms to allow

practice, repetition, and feedback, is essential. Improved teaching methods using simulation-based training aids are effective.⁴⁷ The routine incorporation of handheld echocardiographic techniques and/or spectral display of the heart sounds may improve learner performance. Whether the handheld ultrasound device will replace the stethoscope remains to be seen. Continued improvements in the technical performance characteristics and declining costs of these devices are attractive features, as is the possibility of initiating treatment at the point of care without the need for additional testing in many cases.^{48,49}

The technology and the clinical usefulness of the electrocardiogram (ECG) have continuously advanced over the past two centuries. Early demonstrations of the heart's electrical activity during the last half of the 19th century were closely followed by direct recordings of cardiac potentials by Waller in 1887. Invention of the string galvanometer by Einthoven in 1901 provided a direct method for registering electrical activity of the heart in humans. By 1910, the ECG had emerged from the research laboratory into the clinic and soon became the most commonly used cardiac diagnostic test.

Recent advances have extended the importance of the ECG. It is a vital test for determining the presence and severity of acute myocardial ischemia, localizing sites of origin and pathways of tachyarrhythmias, assessing therapeutic options for patients with heart failure, and identifying and evaluating patients with genetic diseases who are prone to arrhythmias. Although other techniques have evolved to assess cardiac structure, the ECG remains the basic method to assess the heart's electrical activity. Achievements in physiology and technology have expanded the information about the heart's electrical activity that can be derived from the ECG and will extend these clinical applications.

This chapter reviews the physiologic bases for ECG patterns in health and in disease, outlines the criteria for the most common ECG diagnoses in adults, describes critical aspects of its clinical application, and suggests future opportunities for the practice of electrocardiography.

FUNDAMENTAL PRINCIPLES

The ECG is the final outcome of a complex series of physiologic and technologic processes. First, transmembrane ionic currents are generated by ion fluxes across cell membranes and between adjacent cells. These currents are synchronized by cardiac activation and recovery sequences to generate a cardiac electrical field in and around the heart that varies with time during the cardiac cycle. This electrical field passes through numerous other structures, including the lungs, blood, and skeletal muscle, that perturb the cardiac electrical field.

The currents reaching the skin are then detected by electrodes placed in specific locations on the extremities and torso that are configured to produce leads, representing the difference in potentials sensed by pairs of electrodes or electrode combinations. The outputs of these leads are amplified, filtered, and displayed, using a variety of devices, to produce an ECG recording. In computerized systems, these signals are digitized, stored, and processed by pattern recognition software. Diagnostic criteria are then applied, either manually or with the aid of a computer, to produce a preliminary interpretation.

Genesis of Cardiac Electrical Fields

Ionic Currents and Cardiac Electrical Field Generation During Activation. Transmembrane ionic currents (see Chapter 33) are

ultimately responsible for the potentials that are recorded as an ECG. The process of generating the cardiac electrical field during activation is illustrated in Figure 12-1. A single cardiac fiber, 20 mm in length, is activated by a stimulus applied to its leftmost margin (Fig. 12-1A). Transmembrane potentials (V_m) are recorded as the difference between intracellular and extracellular potentials (Φ_i and Φ_o , respectively).

Figure 12-1B plots V_m along the length of the fiber at the instant (t_0) at which activation has reached the point designated as X_0 . As each site is activated, it undergoes depolarization, and the polarity of the transmembrane potential converts from negative to positive, as represented in the typical cardiac action potential. Thus sites to the left of the point X_0 that have already undergone excitation have positive transmembrane potentials (i.e., the inside of the cell is positive relative to the outside of the cell), whereas those to the right of X_0 that remain in a resting state have negative transmembrane potentials. Near the site undergoing activation (site X_0), the potentials reverse polarity over a short distance.

Figure 12-1C displays the direction and magnitude of transmembrane currents (I_m) along the fiber at the instant (t_0) at which excitation has reached site X_0 . Cardiac electrophysiologic currents are considered to be the movement of positive charge. Current flow is inwardly directed in fiber regions that have just undergone activation (i.e., to the left of point X_0) and outwardly directed in neighboring zones still at rest (i.e., to the right of X_0). Sites of outward current flow are current sources and those with inward current flow are current sinks. As depicted in the figure, current flow is most intense in each direction near the site of activation, X_0 .

Because the border between inwardly and outwardly directed currents is relatively sharp, these currents may be visualized as if they were limited to the sites of maximal current flow, as depicted in Figure 12-1D, and separated by a small distance, d , which usually is 1.0 mm or less. As activation proceeds along the fiber, the source-sink pair moves to the right, that is, in the direction of activation, at the speed of propagation in the fiber.

Cardiac Wave Fronts. This example from one cardiac fiber can be generalized to the more realistic case in which multiple adjacent fibers are activated in synchrony to produce an activation wave front. The electrical fields generated by a wave front can be represented by a single vector (or *dipole*) with a strength and orientation equal to the vector sum of all of the fields generated by each of the simultaneously active fibers.

Such an activation wave front generates an electrical field that is characterized by positive potentials ahead of the front and negative potentials behind it. This relationship between the direction of movement of an activation wave front and the polarity of potentials is critical in electrocardiography: An electrode senses positive potentials when an activation front is moving toward it and negative potentials when the activation front is moving away from it.

The potential recorded by an electrode at any site within this field is directly proportional to the average rate of change of intracellular potential as determined by action potential shapes and the size of the

FIGURE 12-1 Example of potentials and currents generated by the activation of a single (e.g., ventricular) cardiac fiber. **A**, Intracellular (Φ_i) and extracellular (Φ_e) potentials are recorded with a voltmeter (V_m) from a fiber 20 mm in length. The fiber is stimulated at site $X = 0$ mm, and propagation proceeds from left to right. **B**, Plot of transmembrane potential (V_m) at the instant in time at which activation reaches point X_0 as a function of the length of the fiber. Positive potentials are recorded from activated tissue to the left of site X_0 , and negative ones are registered from not-yet-excited areas to the right of site X_0 . **C**, Membrane current (I_m) flows along the length of the fiber at time t_0 . The outward current is the depolarizing current that propagates ahead of activation site X_0 , whereas an inward one flows behind site X_0 . **D**, Representation of the sites of peak inward and outward current flow as two point sources, a sink (at the site of peak inward current flow) and a source (at the site of peak outward current flow) separated by distance d . The vector or dipole produced by the source-sink pair is represented by the arrow. (Modified from Barr RC: *Genesis of the electrocardiogram*. In MacFarlane PW, Veitch Lawrie TD [eds]: *Comprehensive Electrocardiography*. New York, Pergamon Press, 1989.)

wave front; inversely proportional to the square of the distance from the activation front to the recording site; and directly proportional to the cosine of the angle between the axis of the direction of activation and a line drawn from that axis to the recording site.

Cardiac Electrical Field Generation During Ventricular Recovery. The cardiac electrical field during recovery (phases 1 through 3 of the action potential—see Chapter 33) is generated by forces analogous to those described during activation. However, recovery differs in several important ways from activation, including the orientation, strength, and propagation speed of the wave front.

First, intercellular potential differences and, hence, the directions of current flow during recovery are the opposite of those described for activation. As a cell undergoes recovery, its intracellular potential becomes progressively more negative. For two adjacent cells, the intracellular potential of the cell whose recovery has progressed further is more negative than that of the adjacent, less recovered cell. Intracellular currents then flow from the less recovered toward the

more recovered cell—that is, recovery wave fronts will have an orientation opposite that of activation wave fronts.

The strength of the recovery front also differs from that of the activation front. As noted earlier, the strength of a wave front is proportional to the rate of change in transmembrane potential. Rates of change in potential during the recovery phases of the action potential are considerably slower than during activation, so that the strength of the recovery fronts at any one instant during recovery is less than during activation.

A third difference between activation and recovery is the rate of movement of the activation and recovery wave fronts. Activation is rapid (as short as 1 millisecond in duration) and occurs over only a small distance along the fiber. Recovery, by contrast, lasts 100 milliseconds or longer and occurs simultaneously over extensive portions of the heart.

These features result in characteristic electrocardiographic differences between activation and recovery patterns. All other factors being equal (an assumption that often is not true, as described later), ECG waveforms generated during recovery of a linear fiber with uniform recovery properties would be of opposite polarity, lower amplitude, and longer duration in comparison with those generated by activation. As described further on, these features are explicitly demonstrated in the clinical ECG.

Role of Transmission Factors. These activation and recovery fields exist within a complex three-dimensional physical environment, referred to as the volume conductor, which modifies the cardiac electrical field. The contents of the volume conductor are called *transmission factors* to emphasize their effects on transmission of the cardiac electrical field throughout the body.

They may be grouped into four broad categories—cellular factors, cardiac factors, extracardiac factors, and physical factors. *Cellular* factors determine the intensity of current fluxes that result from local transmembrane potential gradients. Lower concentrations of the sodium ion, for example, reduce the intensity of current flow and reduce extracellular potentials.

Cardiac factors affect the relationship of one cardiac cell to another. The two major factors are (1) the more rapid propagation of activation along the length of a fiber than across its width, resulting in greater current flow in that direction, and (2) the presence of connective tissue between cardiac fibers that disrupts efficient electrical coupling of adjacent fibers. Recording electrodes oriented along the long axis of a cardiac fiber register higher potentials than for electrodes oriented perpendicular to the long axis. Waveforms recorded from fibers with little or no intervening connective tissue are narrow in width and smooth in contour, whereas those recorded from tissues with abnormal fibrosis are prolonged, with prominent notching.

Extracardiac factors encompass all the tissues and structures that lie between the activation region and the body surface, including the ventricular walls, intracardiac blood, lungs, skeletal muscle, subcutaneous fat, and skin. These tissues alter the cardiac field because of differences in the electrical resistivity of adjacent tissues to produce electrical inhomogeneities within the torso. For example, intracardiac blood has much lower resistivity ($162 \Omega \text{ cm}$) than the lungs ($2150 \Omega \text{ cm}$). Differences in torso inhomogeneities can have significant effects on ECG potentials, especially when the differences are exaggerated as in obese persons.

Other transmission factors reflect basic laws of physics (i.e., *physical* factors). Potential magnitudes change in proportion to the square of the distance between the heart and recording electrode. A related factor is the eccentricity of the heart within the chest. The right ventricle and anteroapical aspect of the left ventricle are closer to the anterior chest wall than are other parts of the left ventricle and atria. Therefore ECG potentials will be higher on the anterior than on the posterior chest, and waveforms projected from the anterior left ventricle to the chest wall will be greater than those generated by posterior regions.

An additional physical factor affecting the recording of cardiac signals is cancellation. When two or more wave fronts that are simultaneously active during activation (or repolarization) have different orientations, the vectorial components of the wave fronts are oriented in opposite directions. These forces cancel each other when viewed from remote electrode positions. The magnitude of this effect is substantial. During both the QRS and ST-T waves, as much as 90% of cardiac activity is obscured by cancellation.

As a result of all of these factors, body surface potentials have an amplitude of only 1% of the amplitude of transmembrane potentials, are smoothed in detail so that surface potentials have only a general spatial relationship to the underlying cardiac events, preferentially

reflect electrical activity in some cardiac regions over others, and manifest only limited amounts of total cardiac electrical activity.

Recording Electrodes and Leads

Potentials generated by the cardiac electrical generator and modified by transmission factors are sensed by electrodes placed on the torso that are configured to form various types of leads.¹

Electrode Characteristics. ECG potentials are affected by the properties of the dermal and epidermal layers of the skin, the electrode itself, and the mechanical contact between the electrode and skin. The net effect is equivalent to a complex electrical circuit that includes resistances, capacitances, and voltages produced by these different components and the interfaces between them. In clinical practice, using an electrolytic paste and cleaning the skin with a mild abrasive can improve electrode-skin contact and reduce the artifacts produced by these factors.

Electrocardiographic Lead Systems. The standard clinical ECG is recorded from electrodes placed on each of the four extremities and six placed on the chest. These electrodes are connected to form leads that record the potential difference between two electrodes (or, as described later, electrode sets). One electrode is designated as the positive input. The potential at the other, or negative, electrode (or electrode set) is subtracted from the potential at the positive electrode to yield the bipolar potential. The actual potential at either electrode is not known, and only the difference between them is recorded. The American Heart Association (AHA) and other cardiology societies recommend that all ECG leads be referred to as *bipolar* leads, because they register the potential difference between two electrodes.*

In some cases, as described later, multiple electrodes are electrically connected together to represent the negative member of the bipolar pair. This electrode network or compound electrode is referred to as a reference electrode. The lead then records the potential difference between a single electrode serving as the positive input, the exploring electrode, and the potential in the reference electrode.

The clinical ECG is performed using 12 such leads: three standard limb leads (leads I, II, and III), six precordial leads (leads V₁ through V₆), and three augmented limb leads (leads aVR, aVL, and aVF). Specifics of electrode placement and definitions of the positive and negative inputs for each lead are presented in **Table 12-1**.

Standard Limb Leads. The standard limb leads record the potential differences between two limbs, as detailed in **Table 12-1** and illustrated in **Figure 12-2** (top). Lead I represents the potential difference between the left arm (positive electrode) and right arm (negative electrode), lead II displays the potential difference between the left leg (positive electrode) and right arm (negative electrode), and lead III represents the potential difference between the left leg (positive electrode) and left arm (negative electrode). The electrode on the right leg serves as an electronic reference that reduces noise and is not included in these lead configurations.

The electrical connections for these leads form a triangle, known as the Einthoven triangle. In it, the potential in lead II equals the sum of potentials sensed in leads I and III, as shown by this equation:

I + II = III

This relationship is known as Einthoven’s law or Einthoven’s equation.

Precordial Leads and the Wilson Central Terminal. The precordial leads register the potential at each of the six designated torso sites (see **Fig. 12-2**, bottom, left panel) in relation to a reference potential. To accomplish this, an exploring electrode is placed on each precordial site and connected to the positive input of the recording system (see **Fig. 12-2**, bottom right). The negative input is the mean value of the potentials recorded at each of the three limb electrodes, referred to as the Wilson central terminal (WCT).†

The potential in each V lead can be expressed as

V_i = E_i – WCT

*As noted further on, in some texts these lead configurations are referred to as *unipolar* leads, following their historical nomenclature. To avoid confusion, one can simply use the generic term “lead.”

†The precordial electrodes and the augmented limb leads (see later) often are referred to as “unipolar” leads. Unipolar leads register the potential at one site in relation to an absolute zero potential. Referring to these leads as unipolar leads is based on the notion that the reference electrode—that is, the Wilson central terminal or the combination of two limb electrodes—represents a true zero potential. Describing these leads as bipolar reflects the recognition that the reference electrode is not at zero potential; rather, it yields the average of the potentials sensed at the sites of the electrodes making up the compound electrode.

TABLE 12-1 Location of Electrodes and Lead Connections for the Standard 12-Lead Electrocardiogram and Additional Leads

LEAD TYPE	POSITIVE INPUT	NEGATIVE INPUT
Standard Limb Leads*		
I	Left arm	Right arm
II	Left leg	Right arm
III	Left leg	Left arm
Augmented Limb Leads		
aVR	Right arm	Left arm plus left leg
aVL	Left arm	Right arm plus left leg
aVF	Left leg	Left arm plus right arm
Precordial Leads†		
V ₁	Right sternal margin, fourth intercostal space	Wilson central terminal
V ₂	Left sternal margin, fourth intercostal space	Wilson central terminal
V ₃	Midway between V ₂ and V ₄	Wilson central terminal
V ₄	Left midclavicular line, 5th intercostal space	Wilson central terminal
V ₅	Left anterior axillary line at the same horizontal plane as for the V ₄ electrode‡	Wilson central terminal
V ₆	Left midaxillary line at the same horizontal plane as for the V ₄ electrode	Wilson central terminal
V ₇	Posterior axillary line at the same horizontal plane as for the V ₄ electrode	Wilson central terminal
V ₈	Posterior scapular line at the same horizontal plane as for the V ₄ electrode	Wilson central terminal
V ₉	Left border of spine at the same horizontal plane as for the V ₄ electrode	Wilson central terminal

*Limb electrodes should be placed near the wrists and ankles or, at a minimum, distal to the shoulders and hips.

†The right-sided precordial leads V₃R to V₆R are placed in mirror image positions on the right side of the chest.

‡If the anterior axillary line is difficult to delineate, the electrode may be placed midway between the V₄ and V₆ electrode positions.

where

WCT = (LA + LL + RA) / 3

and V_i is the potential recorded in precordial lead i, E_i is the voltage sensed at the exploring electrode for lead V_i, and WCT is the potential in the composite Wilson central terminal. Thus the potential in the Wilson central terminal is the average of the potentials in the three limb leads.

The potential recorded by the Wilson central terminal remains relatively constant during the cardiac cycle, so that the output of a precordial lead is determined predominantly by time-dependent changes in the potential at the precordial site. The waveforms registered by these leads preferentially reflect potentials generated in cardiac regions near the electrode, with lesser contributions by those generated by more distant cardiac sources active at any instant during the cardiac cycle.

Precordial electrode placement in women with large breasts may be problematic. Most often, the electrodes are placed beneath the breasts, to reduce attenuation of recorded voltages and to reduce motion artifact.¹

Augmented Limb Leads. The three augmented limb leads are designated aVR, aVL, and aVF. The exploring electrode (**Fig. 12-3**) that

FIGURE 12-2 Top, Electrode connections for recording the standard limb leads I, II, and III. R, L, and F indicate locations of electrodes on the right arm, left arm, and left foot, respectively. Bottom, Electrode locations and electrical connections for recording a precordial lead. Left, The positions of the exploring electrode (V) for the six precordial leads. Right, Connections to form the Wilson central terminal for recording a precordial (V) lead. Five-thousand ohm resistors (5k) are connected to each limb electrode when constructing the Wilson central terminal.

FIGURE 12-3 Electrode locations and electrical connections for recording the augmented limb leads aVR, aVL, and aVF. Dotted lines indicate connections to generate the reference electrode potential.

forms the positive input is the right arm electrode for lead aVR, the left arm electrode for lead aVL, and the left leg electrode for aVF. The reference potential for the augmented limb leads is formed by connecting the two limb electrodes that are not used as the exploring electrode. For lead aVL, for example, the exploring electrode is on the left arm and the reference electrode is the combined output of the electrodes on the right arm and the left foot.

Thus

$$aVR = RA - (LA + LL) / 2$$

$$aVL = LA - (RA + LL) / 2$$

and

$$aVF = LL - (RA + LA) / 2$$

This modified reference system was designed to produce a larger-amplitude signal than if the full Wilson central terminal were used as the reference electrode. When the Wilson central terminal was used, the output was small, in part because the same electrode potential was included in both the exploring and the reference potential inputs. Eliminating this duplication results in a theoretical increase in amplitude of 50%.

The three standard limb leads and the three augmented limb leads are aligned in the frontal plane of the torso. The six precordial leads are aligned in the horizontal plane of the chest.

As described previously, individual extremity electrodes are included in more than one lead. This results in significant redundancy in the information recorded by the six frontal plane leads. The previous lead equations indicate that all six frontal plane leads can be computed from recordings at any two limb leads. Indeed, ECG machines commonly record potentials from only two of the three limb electrodes and then compute the potentials in all six frontal plane leads. By contrast, each of the six precordial electrodes provides unique information without such redundancy.¹

The 12 leads are commonly divided into subgroups corresponding to the cardiac regions to which they are thought to be most sensitive. Various definitions of these groupings have been offered in the literature. For example, anterior lead groups have been defined as including V_2 through V_4 or only V_2 and V_3 , and leads I and aVL have been described as being lateral or anterobasal. These designations are non-specific, and the recommendation of expert committees has been not to use them in ECG interpretation, except in the case of localizing myocardial infarction.²

Other Lead Systems. Other lead systems have been developed to detect diagnostically important information not recorded by the standard 12-lead ECG and to increase the efficiency of recording, transmitting, and storing an ECG. Such systems include expanded lead sets that include leads in addition to the standard 12 leads and lead sets based on electrodes in nonstandard locations.

Expanded lead systems include the recording of additional right precordial leads to assess right ventricular abnormalities, such as right ventricular infarction in patients with evidence of inferior infarction,² and left posterior leads (see Table 12-1) to detect acute posterolateral infarctions.

Other expanded systems include electrode arrays of 80 or more electrodes deployed on the anterior and posterior torso to display body surface potentials as body surface isopotential maps. These maps portray cardiac potentials over broader areas of the torso than those included in routine electrocardiography. This additional information may have diagnostic importance improving the accuracy of, for example, detecting ST-segment elevation acute myocardial infarction.³

Other lead sets are based on electrode configurations that differ from those in the standard ECG. These have sought to minimize movement artifacts during exercise and long-term monitoring by placing limb electrodes on the torso rather than on the limbs, and to reduce the number of electrodes to decrease the time and mechanical complexity of a full recording during emergency situations and long term monitoring.⁴ Specific examples are discussed in other chapters.

Although these lead sets do meet specific needs in certain clinical situations, the waveforms they produce are significantly different from

those recorded from the standard ECG sites. Placing limb electrodes on the torso, for example, alters the characteristics of the limb lead electrodes as well reference electrodes used for the precordial and augmented limb leads and thereby impact all twelve leads. The result is significantly altered frontal plane QRS and ST-T wave patterns that change the mean QRS axis with impact on the diagnostic criteria for, for example, ventricular hypertrophy and myocardial infarction.⁵ Thus, although these modified lead sets offer advantages under specific clinical conditions, they should not be used to record a diagnostic ECG.

Other lead systems that have had clinical usefulness include those designed to record a vectorcardiogram (VCG). The VCG depicts the orientation and strength of a single cardiac dipole or vector that best represents overall cardiac activity at each instant during the cardiac cycle. Lead systems for recording the VCG record the three orthogonal or mutually perpendicular components of the dipole moment—the horizontal (x), frontal (y), and sagittal or anteroposterior (z) axes. Clinical use of the VCG has waned in recent years, but as described later, vectorial principles remain important for understanding the origins of ECG waveforms.

Lead Vectors and Heart Vectors. A lead can be represented as a vector referred to as the lead vector. For simple two-electrode leads, such as leads I, II, and III, the lead vectors are directed from the negative electrode toward the positive one (Fig. 12-4). For the augmented limb and precordial leads, the origin of the lead vectors lies at the midpoint of the axis connecting the electrodes that comprise the compound electrode. That is, for lead aVL, the vector points from the midpoint of the axis connecting the right arm and left leg electrodes toward the left arm (Fig. 12-4, left). For each precordial lead, the lead vector points from the center of the triangle formed by the three standard limb leads to the precordial electrode site (Fig. 12-4, right).

As described earlier, instantaneous cardiac activity also can be approximated as a single vector (the heart vector) representing the vector sum of the various active wave fronts. Its location, orientation, and intensity vary from instant to instant as cardiac activation proceeds.

The amplitude of the potentials sensed in a lead equals the length of the projection of the heart vector on the lead vector, multiplied by the length of the lead vector:

$$V_L = (H)(\cos \theta)(L)$$

where L and H are the length of the lead and heart vectors, respectively, and θ is the angle between the two vectors, as illustrated in Figure 12-5. Thus, if the projection of the heart vector on the lead vector points toward the positive pole of the lead axis, the lead will record a positive potential. If the projection is directed away from the positive pole of the lead axis, the potential will be negative. If the projection is perpendicular to the lead axis, the lead will record zero potential.

FIGURE 12-4 Lead vectors for the three standard limb leads, the three augmented limb leads (left), and the six unipolar precordial leads (right). LA = left arm; LF = left foot; RA = right foot.

FIGURE 12-5 The heart vector H and its projections on the lead axes of leads I and III. Voltages recorded in lead I will be positive, and potentials in lead III will be negative. LA = left arm; LF = left foot; RA = right arm.

FIGURE 12-6 The hexaxial reference system constructed from the lead axes of the six frontal plane leads. The lead axes of the six frontal plane leads have been rearranged so that their centers overlie one another. These axes divide the plane into 12 segments, each subtending 30 degrees. Positive ends of each axis are labeled with the name of the lead.

Hexaxial Reference Frame and Electrical Axis. The lead axes of the six frontal plane leads can be superimposed to produce the hexaxial reference system. As depicted in **Figure 12-6**, the six lead axes divide the frontal plane into 12 segments, each subtending 30 degrees.

These concepts allow calculation of the mean electrical axis of the heart. The orientation of the mean electrical axis represents the direction of activation in an “average” cardiac fiber. This direction is determined by the properties of the cardiac conduction system and activation properties of the myocardium. Differences in the relation of cardiac to torso anatomy contribute relatively little to shifts in the axis. As described further on, this measurement is an important part of diagnostic criteria for chamber enlargement and conduction system defects.

The process for computing the mean electrical axis during ventricular activation in the frontal plane is illustrated in **Figure 12-7**. First, the mean force during activation is represented by the area under the QRS waveform, measured as millivolt-milliseconds. Areas above the baseline are assigned a positive polarity and those below the baseline

FIGURE 12-7 Calculation of the mean electrical axis during the QRS complex from the areas under the QRS complex in leads I and III. Magnitudes of the areas of the two leads are plotted as vectors on the appropriate lead axes, and the mean QRS axis is the sum of these two vectors. (From Mirvis DM: *Electrocardiography: A Physiologic Approach*. St. Louis, Mosby-Year Book, 1993.)

have a negative polarity. The overall area equals the sum of the positive and the negative areas.

Second, the area in each lead (typically, two are chosen) is represented as a vector oriented along the appropriate lead axis in the hexaxial reference system (see **Fig. 12-6**), and the mean electrical axis equals the resultant or vector sum of the two vectors. An axis directed toward the positive end of the lead axis of lead I—that is, oriented directly away from the right arm and toward the left arm—is designated as an axis of 0 degrees. Axes oriented in a clockwise direction from this zero level are assigned positive values, and those oriented in a counterclockwise direction are assigned negative values.

The mean electrical axis during ventricular activation in the horizontal plane can be computed in an analogous manner by using the areas under and lead axes of the six precordial leads (see **Fig. 12-4**, right). A horizontal plane axis located along the lead axis of lead V_6 is assigned a value of 0 degrees, and those directed more anteriorly have positive values.

This process can be applied to compute the mean electrical axis for other phases of cardiac activity. Thus the mean force during atrial activation is represented by the areas under the P wave, and the mean force during ventricular recovery is represented by the areas under the ST-T wave.

Electrocardiographic Processing and Display Systems

ECG recording using computerized systems involves six steps: (1) signal acquisition; (2) data transformation; (3) waveform recognition and feature extraction; (4) diagnostic classification; (5) data compression and storage; and (6) display of the final ECG.¹

Signal Acquisition. Signal acquisition steps include amplifying the recorded signals, converting the analog signals into digital form, and filtering the signals to reduce noise. The standard amplifier gain for routine electrocardiography is 1000. Lower (e.g., 500 or half-standard) or higher (e.g., 2000 or double-standard) gains may be used to compensate for unusually large or small signals, respectively.

Analog signals are converted to a digital form at rates of 1000/second (1000 Hz) to as high as 15,000 Hz. Too low a sampling rate will miss brief signals such as notches in QRS complexes or pacemaker spikes and will result in altered waveform morphologies. Too fast a sampling rate may introduce artifacts, including high-frequency noise, and will generate excessive amounts of data necessitating extensive digital storage capacity.

ECG potentials are then filtered to reduce unwanted, distorting signals. Low-pass filters reduce the distortions caused by high-frequency interference from, for example, muscle tremor and external electrical devices; high-pass filters reduce the effects of body motion or respiration. For routine electrocardiography, the standards set by professional groups require an overall bandwidth of 0.05 to 150 Hz for adults.¹ Narrower filter settings, such as 1 to 30 Hz, as commonly used in rhythm monitoring, will reduce baseline wander related to motion and respiration but may result in significant distortion of both the QRS complex (including width, amplitude, and Q wave patterns) and the ST-T wave.¹

ECG amplifiers include a capacitor stage between the input and output; that is, they are capacitor-coupled. This configuration blocks unwanted direct current (DC) potentials, such as those produced by the electrode interfaces, while permitting flow of alternating current (AC) signals, which account for the waveform shape. The elimination of the DC potential from the final product means that ECG potentials are not calibrated against an external reference level (e.g., a ground potential). Rather, ECG potentials are measured in relation to another portion of the waveform that serves as a baseline. The TP segment, which begins at the end of the T wave of one cardiac cycle and ends with the onset of the P wave of the next cycle, usually is the most appropriate internal ECG baseline (e.g., for measuring ST-segment deviation).

Data Transformation. Multiple cardiac cycles are recorded for each lead and are processed to form a single representative beat for each lead that is used for interpretation. This step reduces the effects of beat-to-beat variation in the waveforms. The representative beats from all leads may then be electronically overlaid on each other to produce a single, global pattern. ECG intervals are then measured from this single pattern to identify the earliest onset and latest ending of an interval in all leads.

Waveform Identification and Feature Extraction. This step includes determining the beginning and end of each of the ECG waves and intervals, and the measurement of waveform amplitudes and intervals.

Diagnostic Classification. The interval and amplitude measurements are then compared with specific diagnostic criteria to establish the interpretation of the ECG. In some cases, the criteria are derived from physiologic constructs and constitute the sole basis for a diagnosis, with no anatomic or physiologic correlation. For example, the criteria for intraventricular conduction defects (see later) are diagnostic without reference to an anatomic standard.

For other diagnoses, the criteria are based on statistical correlations between anatomic or physiologic findings and ECG measurements in large populations. For example, the diagnostic criteria for ventricular hypertrophy depend on correlations between various ECG patterns and anatomic measures of chamber size, in large populations, as noted. For these criteria, the final diagnosis is not absolute but represents a statistical probability that the structural abnormality exists on the basis of the presence or absence of a specific set of ECG findings. A lexicon of preferred diagnostic statements was proposed in 2007.⁶

Data Compression and Storage. Algorithms are used to compress the digital data to reduce both transmission time and storage requirements. Compression ratios of 8:1 or greater can be achieved while retaining waveform fidelity.

Display. Cardiac potentials most commonly are displayed as the classic scalar ECG, which depicts the potentials recorded from each

lead as a function of time. For standard electrocardiography, amplitudes are displayed on a scale of 1 mV to 10 mm on the vertical axis and time as 400 msec/cm on the horizontal scale. Leads generally are displayed in three groups—the three standard limb leads, followed by the three augmented limb leads, followed by the six precordial leads.

Alternative display formats have been proposed in which the six limb leads are displayed in the sequence of the frontal plane reference frame (see Fig. 12-6).⁷ In addition, the polarity of lead aVR is reversed. That is, waveforms are displayed in this order: lead aVL, lead I, lead aVR (reversed in polarity), lead II, lead aVF, and lead III. Advantages of this system may include facilitating estimation of the electrical axis by presenting the leads in the order in which they appear on the frontal plane reference frame and emphasizing the relevance of abnormalities in lead aVR by reversing its polarity.

THE NORMAL ELECTROCARDIOGRAM

The waveforms and intervals that make up the standard ECG are displayed in Figure 12-8, and a normal 12-lead ECG is shown in Figure 12-9. The *P* wave is generated by activation of the atria, the

FIGURE 12-8 The waves and intervals of a normal electrocardiogram. (From Goldberger AL: *Clinical Electrocardiography: A Simplified Approach*. 7th ed. St. Louis, CV Mosby, 2006.)

FIGURE 12-9 Normal electrocardiogram recorded from a 48-year-old woman. The vertical lines of the grid represent time, with lines spaced at 40-millisecond intervals. Horizontal lines represent voltage amplitude, with lines spaced at 0.1-mV intervals. Every fifth line in each direction typically is darkened (not shown here). The heart rate is approximately 76 beats/minute (with physiologic variations due to respiratory sinus arrhythmia); the PR interval, QRS, and QTc durations measure approximately 140, 84, and 400 milliseconds, respectively; and the mean QRS axis is approximately +35 degrees.

TABLE 12-2 Normal Values for Durations of Electrocardiographic Waves and Intervals in Adults

WAVE OR INTERVAL	DURATION (MSEC)
P wave duration	<120
PR interval	<200
QRS duration	<110-120*
QT interval (corrected)	≤440-450*

*See text for further discussion.

PR segment corresponding to the duration of atrioventricular conduction, the *QRS complex* is produced by the activation of the two ventricles, and the *ST-T wave* reflects ventricular recovery.

Table 12-2 lists normal values for the various intervals and waveforms of the ECG. The range of normal values of these measurements reflects the substantial interindividual variability related to, among other factors, differences in age, sex, body habitus, heart orientation, and physiology. In addition, significant intraindividual differences in ECG patterns may occur between ECGs recorded days, hours, or even minutes apart owing to technical issues (e.g., changes in electrode position) or the biologic effects of changes in posture, temperature, or eating.⁸

The values shown in **Table 12-2** typically have been used in clinical electrocardiography. Other normal ranges for various measures, as described in the sections that follow, have been suggested based on changes in the demographics of the population over time, as well as differences in recording methods, especially the use of digital signals and computerized analysis systems over the past decades. Computerization of ECG interpretation facilitates the identification and use of different criteria for various population subgroups based on, for example, age, sex, and race. The specialized nature of these datasets suggests that a single range of normal values for all subjects may be inappropriate, potentially leading to errors in diagnosis of clinically important conditions.⁹

Atrial Activation and the P Wave

Atrial Activation. Atrial activation begins with impulse generation in the atrial pacemaker complex in or near the sinoatrial node (see **Chapter 33**). Once the impulse leaves this pacemaker site, atrial activation begins in one area or, in many cases, simultaneously in several areas of the right atrium. Propagation then proceeds rapidly along the crista terminalis and moves anteriorly toward the lower portion of the right atrium.

Interatrial spread is more complex. In most people, the left atrium is activated first by propagation across Bachmann's bundle, which extends from the anterior right atrium, above the fossa ovalis, to the left atrium near the right upper pulmonary vein. Other routes of interatrial spread include paths within the fossa ovalis or near the coronary sinus either alone or, more commonly, in combination with conduction in Bachmann's bundle.

At the same time, activation spreads through the interatrial septum, beginning high on the right side and moving around the fossa ovalis to reach the top of the interventricular septum. The last area to be activated is the inferolateral left atrium.

Thus right atrial activation begins before activation of the left atrium, left atrial activation continues after the end of right atrial activation, and both atria undergo activation during much of the middle of the overall atrial activation period.

The Normal P Wave

These patterns of atrial activation produce the normal P wave. Activation beginning high in the right atrium and proceeding simultaneously leftward toward the left atrium and inferiorly toward the atrioventricular node corresponds to a mean frontal plane P wave axis of approximately 60 degrees. Based on this orientation of the heart vector, normal atrial activation projects positive P waves in leads II and usually in leads I, aVL, and aVF. The pattern in leads aVL and III may be upright or downward, depending on the exact orientation of the mean P wave axis.

P wave patterns in the precordial leads correspond to the direction of atrial activation wave fronts in the horizontal plane. Atrial activation early in the P wave is over the right atrium and is oriented primarily anteriorly. Later, it shifts posteriorly as activation proceeds over the left atrium. Thus the P wave in the right precordial leads (V_1 and, occasionally, V_2) is upright or, often, biphasic with an initial positive deflection followed by a later negative one. In the more lateral leads, the P wave is upright and reflects continual right to left spread of the activation fronts. Variations in this pattern may reflect differences in pathways of interatrial conduction.¹⁰

The upper limit for a normal P wave duration is conventionally set at 120 milliseconds as measured in the lead with the widest P wave. The amplitude in the limb leads normally is less than 0.25 mV and the terminal negative deflection in the right precordial leads normally is less than 0.1 mV in depth.

Atrial Repolarization

The potentials generated by atrial repolarization are not usually seen on the surface ECG because of their low amplitude (usually less than 100 μ V) and because they are superimposed on the much higher-amplitude QRS complex.¹¹ They may be observed as a low-amplitude wave with a polarity opposite that of the P wave (the T_a wave) during atrioventricular block. Deviation of the PR segment has special significance in influencing ST-segment patterns during exercise testing and as an important marker of acute pericarditis or atrial infarction, as discussed later.

Heart Rate Variability

Analysis of beat-to-beat changes in heart rate and related dynamics, termed *heart rate variability*, can provide insight into neuroautonomic control mechanisms and their perturbations with aging, disease, and drug effects. For example, relatively high-frequency (0.15 to 0.5 Hz) fluctuations mediated primarily by vagus nerve traffic occur phasically, with heart rate increasing during inspiration and decreasing during expiration. Attenuation of this respiratory sinus arrhythmia at rest is a marker of physiologic aging and also occurs with diabetes mellitus, congestive heart failure, and a wide range of other conditions that alter autonomic tone. Relatively lower-frequency (0.05 to 0.15 Hz) physiologic oscillations in heart rate are associated with baroreflex activation and appear to be jointly regulated by sympathetic and parasympathetic interactions. Various complementary signal processing techniques have been developed to analyze heart rate variability and its interactions with other physiologic signals, including time domain statistics, frequency domain techniques based on spectral methods, and newer computational tools derived from nonlinear dynamics and complex systems theory.¹² (See also the National Institutes of Health [NIH]-sponsored PhysioNet website at www.physionet.org for tutorials and open-source software.)

Atrioventricular Node Conduction and the PR Segment

The *PR segment* is the usually isoelectric region beginning with the end of the P wave and ending with the onset of the QRS complex. It forms part of the *PR interval* extending from the onset of the P wave to the onset of the QRS complex. The overall PR interval is best determined from the lead with the shortest PR intervals (to avoid missing various preexcitation syndromes). The normal PR interval measures 120 to 200 milliseconds in duration in adults.

The PR segment serves as the temporal bridge between atrial activation and ventricular activation. Most of the time, this segment represents slow conduction within the atrioventricular node. On exiting the atrioventricular node, the impulse rapidly traverses the bundle of His to enter the bundle branches, and it then travels through the specialized intraventricular conduction paths to activate ventricular myocardium. The segment ends when enough ventricular myocardium has been activated to initiate the recording of the QRS complex.

The PR segment appears isoelectric because the potentials generated by the conduction system structures are too small to produce detectable voltages on the body surface at amplifier gains used in

clinical electrocardiography. Signals from elements of the conduction system can be recorded from intracardiac recording electrodes placed against the base of the interventricular septum near the bundle of His (see Chapter 33).

Ventricular Activation and the QRS Complex

Normal ventricular activation is a complex process that is dependent on interactions between the physiology and anatomy of both the specialized ventricular conducting system and the ventricular myocardium.

Ventricular Activation

Ventricular activation is the product of two temporally overlapping events—endocardial activation and transmural activation. *Endocardial* activation is guided by the anatomic distribution and physiology of the His-Purkinje system. The broadly dispersed ramifications of this treelike (fractal) system and the rapid conduction within it result in the near-simultaneous activation of multiple endocardial sites and the depolarization of most of the endocardial surfaces of both ventricles within several milliseconds.

The sequence of *ventricular* endocardial activation, depicted in Figure 12-10, is dependent upon the fanlike distribution of the left bundle branch system across the endocardium.¹³ Earliest activity begins in

FIGURE 12-10 Activation sequence of the normal right and left ventricles. Portions of the left and right ventricles have been removed so that the endocardial surfaces of the ventricles and the interventricular septum can be seen. Isochrone lines connect sites that are activated at equal instants after the earliest evidence of ventricular activation. (From Durrer D: *Electrical aspects of human cardiac activity: A clinical-physiological approach to excitation and stimulation*. Cardiovasc Res 2:1, 1968.)

FIGURE 12-11 Schematic representation of ventricular depolarization as two sequential vectors representing septal (left) and left ventricular free wall (right) activation. QRS waveforms generated by each stage of activation in leads V_1 and V_6 are shown.

three sites: (1) the anterior paraseptal wall of the left ventricle, (2) the posterior paraseptal wall of the left ventricle, and (3) the center of the left side of the septum. These loci generally correspond to the sites of insertion of the fascicles of the left bundle branch. Septal activation begins on the left side and spreads across the septum from left to right and from apex to base.

Wave fronts sweep from these initial sites of activation in anterior and inferior and then superior directions to activate the anterior and lateral walls of the left ventricle. The posterobasal areas of the left ventricle are the last to be activated.

Excitation of the right ventricle begins near the insertion point of the right bundle branch near the base of the anterior papillary muscle and spreads to the free wall. The final areas to be activated are the pulmonary conus and the posterobasal areas. Thus, in both ventricles, the overall endocardial excitation pattern begins on septal surfaces and sweeps down toward the apex and then around the free walls to the posterior and basal regions in an apex-to-base direction.

The activation fronts then move from endocardium to epicardium. Excitation of the endocardium begins at sites of Purkinje-ventricular muscle junctions and proceeds by muscle cell to muscle cell conduction in an oblique direction toward the epicardium.

Normal QRS Complex

The sequence of endocardial and transmural activation results in the characteristic waveforms of the QRS complex. QRS patterns are described by the sequence of waves constituting the complex. An initial negative deflection is called the *Q wave*, the first positive wave is the *R wave*, and the first negative wave after a positive wave is the *S wave*. A second upright wave following an S wave is an *R'* as in *R' wave*. Tall waves are denoted by uppercase letters and smaller ones by lowercase letters. A monophasic negative complex is referred to as a *QS complex*. Thus, for example, the overall QRS complex may be described as *qRS* if it consists of an initial small negative wave (the *q wave*) followed by a tall upright one (the *R wave*) and a deep negative one (an *S wave*). In an *RSr' complex*, initial tall R and S waves are followed by a small positive wave (the *r' wave*). In each case, the deflection must cross the baseline to be designated a discrete wave; changes in waveform direction that do not cross the baseline result in *notches*.

Early QRS Patterns. The complex pattern of activation described earlier can be simplified into two vectors, the first representing septal activation and the second representing left ventricular free wall activation (Fig. 12-11). Initial activation of the interventricular septum corresponds to a vector oriented from left to right in the frontal plane and anteriorly in the horizontal plane, corresponding to the anatomic position of the septum within the chest. This vector produces an initial positive wave in leads with axes directed to the right (lead aVR) or anteriorly (lead V_1). Leads with axes directed to the left (leads I, aVL , V_5 , and V_6) will register initial negative waves known as septal q waves. These initial forces are normally of low amplitude and are brief (less than 30 milliseconds in duration). The absence of these septal q waves, with QS complexes evident in the right precordial leads or seen as initial R waves in leads I, V_5 , and V_6 , typically is a normal variant and not associated with any cardiac disease.

Mid- and Late QRS Patterns. Subsequent parts of the QRS complex reflect activation of the free walls of the left and right ventricles. Because right ventricular muscle mass is considerably smaller than that of the left ventricle, it contributes little to normal QRS complexes. Thus the normal QRS can be considered to represent only septal and left ventricular activity, with little meaningful oversimplification.

The complex interrelationships among cardiac position, conduction system function, and ventricular geometry¹³ result in a wide range of normal QRS patterns in the limb leads. The QRS pattern in leads II, III, and aVF may be predominantly upright with qR complexes, or these leads may show rS or RS patterns. Lead I may record an isoelectric RS pattern or a predominantly upright qR pattern.

The wide range of QRS patterns, especially in the inferior leads, can be interpreted by referring to the hexaxial reference system in [Figure 12-6](#). The normal mean QRS axis in adults lies between -30 degrees and $+90$ degrees. If the mean axis is near 90 degrees, the QRS complex in leads II, III, and aVF will be predominantly upright, with qR complexes; lead I will record an isoelectric RS pattern because the heart vector lies perpendicular to the lead axis. If the mean axis is nearer 0 degrees, the patterns will be reversed; leads I and aVL will register predominantly upright qR pattern, and leads II, III, and aVF will show rS or RS patterns.

Mean QRS axes more positive than $+90$ degrees (usually with an rS pattern in lead I) represent *right axis deviation*. Axes between $+90$ and $+120$ degrees are referred to as moderate and those between $+120$ and $+180$ degrees are referred to as marked right axis deviation. Axes more negative than -30 degrees (with an rS pattern in lead II) represent *left axis deviation*, with axes between -30 and -45 degrees called moderate and those between -45 and -90 degrees called marked left axis deviation. Mean QRS axes of approximately -80 to -90 degrees are sometimes referred to as *superior axis deviation* and have been reported in cases of severe chronic obstructive lung disease.

Mean axes lying between -90 degrees and -180 degrees (or, equivalently, between $+180$ degrees and $+270$ degrees) are referred to as *extreme axis deviations* or, alternatively, as right superior axis deviations. The term *indeterminate axis* is applied when all six extremity leads show biphasic (QR or RS) patterns, indicating a mean axis that is perpendicular to the frontal plane. This finding can occur as a normal variant or may be seen in a variety of pathologic conditions.

Normal QRS patterns in the precordial leads follow an orderly progression from right (V_1) to left (V_6). In leads V_1 and V_2 , leftward and posterior activation of the left ventricular free wall generates S waves following the initial r waves generated by septal activation (an rS pattern). These S waves are produced by the spread of activation in the free wall to the left and posteriorly, with generation of a heart vector directed away from the axes of these leads.

Patterns in the midprecordial leads V_3 and V_4 reflect the activation front in the ventricular free wall. It first approaches the exploring electrode and then moves leftward and posteriorly to more remote regions of the left ventricle and away from the exploring electrode. In leads V_3 and V_4 , this generates an R or r wave as it moves toward the electrode, followed by an S wave as it moves away from the electrode to produce rS or RS complexes. As the exploring electrode moves laterally to the left, the R wave becomes more dominant and the S wave becomes smaller (or is totally lost) because of the longer time period during which the activation front moves toward the positive end of the electrode. In the leftmost leads (i.e., leads V_5 and V_6), the normal pattern also includes the septal q wave, to produce a qR or qRs pattern.

Thus, in the precordial leads, the QRS complex usually is characterized by a consistent progression from an rS complex in the right precordial leads to an RS pattern in the midprecordial leads, and to a qR pattern in the left precordial leads. The site at which the pattern changes from an rS to an RS configuration—the lead in which an isoelectric RS pattern is present—is known as the *transition zone* and normally occurs in lead V_3 or V_4 . An example of a normal precordial QRS pattern is shown in [Figure 12-9](#). An altered location of the transition zone may occur for a variety of reasons; transition zones that are shifted to the right to lead V_2 are early transitions, and those that are shifted leftward to V_5 or V_6 are delayed transitions.

Normal variability in QRS amplitudes, axes, and duration QRS are related to demographic and physiologic factors. QRS amplitudes are greater in men than in women, with higher amplitudes in African Americans than in those of other races. In addition, the location of the mitral papillary muscles in relation to the septum affects duration and frontal plane axis,¹³ and left ventricular mass (within the normal range) affects both QRS amplitude and duration.¹⁴ Higher-than-normal amplitudes are characteristic of chamber hypertrophy and conduction defects, as discussed later on. Low-amplitude QRS complexes—that is, complexes with overall amplitudes of less than 0.5 mV in all frontal plane leads and less than 1.0 mV in the precordial leads—may occur as a normal variant or as a result of cardiac (e.g., multiple infarctions, infiltrative cardiomyopathies, myocarditis) or extracardiac (e.g., pericardial effusion, chronic obstructive pulmonary disease, pneumothorax) conditions.¹⁵

QRS Duration

The upper normal value for QRS duration traditionally is set at less than 120 milliseconds (and often at less than 110 milliseconds),

measured in the lead with the widest QRS complex. Women, on average, have somewhat shorter QRS durations than men (by approximately 5 to 8 milliseconds).

The Intrinsicoid Deflection. An additional feature of the QRS complex is the *intrinsicoid deflection*. An electrode overlying the ventricular free wall will record a rising R wave as transmural activation proceeds toward it. Once the activation front reaches the epicardium, the full thickness of the wall under the electrode will be in an active state. At that moment, the electrode will register negative potentials as activation proceeds in remote cardiac areas. The sudden reversal of potential produces a sharp downslope—the intrinsicoid deflection—that approximates the timing of activation of the epicardium under the electrode. The term *ventricular activation time* (VAT) is sometimes used with reference to the surface ECG.

Ventricular Recovery and the ST-T Wave

Sequences of Ventricular Recovery. The ST-T wave reflects activity during the plateau phase (the ST segment) and the later repolarization phases (the T wave) of the cardiac action potential.

Ventricular repolarization, like activation, occurs in characteristic geometric patterns with differences in recovery times between regions of the left ventricle and across the ventricular wall. In general, the repolarization sequence is the opposite of the activation sequence, that is, regions activated later repolarize before areas activated early.

Regional differences in recovery properties reflect shorter action potential durations in the anterobasal region than in the posterolateral region of the left ventricle. This discrepancy results in quicker recovery in the basal than in the apical regions, producing positive current flow toward the apex and positive ST-T waves over the left precordium. The result, in normal persons, is relatively concordant QRS and ST-T wave patterns; that is, the ST-T wave has the same polarity as that of the QRS complex.

Transmural differences in recovery times are the result of differences in action potential duration across the ventricular wall. Repolarization begins in the epicardium and occurs later in the midmyocardial wall and in the endocardium. The resulting current flow will then be directed away from sites of less recovery (the endocardium) toward sites of greater recovery (near the epicardium). The orientation of the resulting current is in the same direction as for transmural activation current, as described earlier. The result, in normal persons, is concordant QRS and ST-T wave patterns.

Some animal and human studies¹⁶ have suggested the presence of midwall cells (M cells) that have action potentials longer than those of endocardial or epicardial cells. In this model, the ST-T wave begins when epicardial cells begin to recover ahead of both M cells and endocardial cells, with current flowing from midmyocardial and endocardial regions toward the epicardium. This initiates the rising portion of the T wave, with the peak of the T wave corresponding to the end of epicardial repolarization.

As endocardial regions begin to repolarize, a second set of currents flowing from M cells to endocardial cells is generated. This current initiates the descending limb of the T wave.

The role of these transmural gradients remains controversial. Although some human studies have documented significant transmural recovery gradients,¹⁶ others¹⁷ have disputed these findings and have concluded that in intact, normal human hearts, transmural gradients are insignificant and that the ST-T wave is the result solely of regional differences in recovery.

The Normal ST-T Wave

The normal ST-T wave begins as a low-amplitude, slowly changing wave (the *ST segment*) that gradually evolves into a larger wave, the *T wave*. The onset of the ST-T wave is the *junction* or *J point*, and it is normally at or near the isoelectric baseline of the ECG (see [Fig. 12-9](#)). The level of the ST segment generally is measured at the J point or, in some applications such as exercise testing, 40 or 80 milliseconds after the J point.

The polarity of the ST-T wave generally is the same as the net polarity of the preceding QRS complex. Thus T waves usually are upright in leads I, II, aVL, and aVF and the lateral precordial leads. They are negative in lead aVR and variable in leads III, V_1 , and V_2 .

The amplitude of the normal J point and ST segment varies with race, sex, and age.^{9,18} It typically is greatest in lead V_2 , and it is higher in young men than in young women and higher in African Americans

than in whites. Recent recommendations for the upper limits of normal J point elevation in leads V_2 and V_3 are 0.2 mV for men 40 years of age or older, 0.25 mV for men younger than 40 years, and 0.15 mV for women. In other leads, the recommended upper limit is 0.1 mV.¹⁸

The J Wave

A J wave is a dome- or hump-shaped wave that appears at the end of the QRS complex and that has the same polarity as the preceding QRS complex. It may be prominent as a normal variant (see later) and in certain pathologic conditions, such as systemic hypothermia (where it is sometimes referred to as an *Osborn wave*) and in a set of conditions commonly referred to as the *J wave syndromes*.¹⁹ These syndromes include the *Brugada patterns* (see Chapters 32 and 37) and the *early repolarization pattern* (discussed later on). Its origin has been correlated with a prominent notch in phase 1 of the action potentials on the epicardium (related to an augmented net outward current, I_{to}) but not on the endocardium, creating a transmural potential gradient leading to QRS notching and ST elevation.

The U Wave

The T wave may be followed by an additional low-amplitude wave known as the *U wave*. This wave, usually less than 0.1 mV in amplitude, normally has the same polarity as the preceding T wave. It is largest in the leads V_1 and V_2 , and most often is seen at slow heart rates. Its electrophysiologic basis is uncertain; it may be caused by the late repolarization of the Purkinje fibers, by the long action potential of midmyocardial M cells, or by delayed repolarization in areas of the ventricle that undergo late mechanical relaxation.

The QT Interval

The QT interval extends from the onset of the QRS complex to the end of the T wave. Thus it includes the total duration of ventricular activation and recovery and, in a general sense, corresponds to the duration of the ventricular action potential.

Accurately measuring the QT interval is challenging for several reasons, including identifying the beginning of the QRS complex and end of the T wave, determining which lead(s) to use, and adjusting the measured interval for rate, QRS duration, and sex.¹⁸ Because the onset of the QRS and the end of the T wave do not occur simultaneously in every lead, the QT interval duration will vary from lead to lead by as much as 50 to 65 milliseconds. In automated ECG systems, the interval typically is measured from a composite of all leads, with the interval beginning with the earliest onset of the QRS in any lead and terminating with the latest end of the T wave in any lead. When the interval is measured from a single lead, the lead in which the interval is the longest (most commonly lead V_2 or V_3) and in which a prominent U wave is absent (usually aVR or aVL) should be used.

The normal QT interval is rate-dependent, decreasing as heart rate increases. This corresponds to rate-related changes in the duration of the normal ventricular action potential duration and refractoriness. Numerous formulas have been proposed to correct the measured QT interval for this rate effect.²⁰ A commonly used formula was developed by Bazett in 1920. The result is a corrected QT interval, or QTc, defined by the following equation:

$$QTc = QT / \sqrt{RR}$$

where the QT and RR intervals are measured in seconds.* The Joint Report of the AHA, the American College of Cardiology (ACC), and other professional organizations¹⁸ has suggested that the upper limit for QTc be set at 460 for women and 450 for men, and that the lower limit be set at 390.

*The QTc traditionally is reported in units of seconds. However, the units of the QTc will vary with the formula used for the rate correction. Based on the Bazett formula, for example, it is a ratio of seconds to the square root of seconds, which yields awkward units of square root of seconds. This inconvenience can be obviated by considering the RR in the denominator as being unitless for this computation.

The Bazett formula has limited accuracy in correcting for the effects of heart rate on the QT interval. Large database studies have, for example, shown that the QTc interval based on the Bazett formula remains significantly affected by heart rate and that as many as 30% of normal ECGs would be diagnosed as having a prolonged QT interval when this formula is used.²¹ The formula, in general, overcorrects the QT interval at high heart rates and undercorrects it at low rates.

Many other formulas and methods for correcting the QT interval for the effects of heart rate, including linear, logarithmic, hyperbolic, and exponential functions, have been proposed. Each has a different normal range. A joint committee of professional organizations has suggested using a linear regression function.¹⁸ Several linear models have been proposed; one formula that has been shown to be relatively insensitive to heart rate is

$$QTc = QT + 1.75(HR - 60)$$

where HR is heart rate and the intervals are measured in milliseconds.

QT prolongation and shortening occur in numerous syndromes, discussed elsewhere in this book, associated with tachyarrhythmias and sudden death (see Chapters 32, 34, and 37), and may vary during the day and between different seasons. A meta-analysis of 23 studies demonstrated that a 50-millisecond increase in the QT interval is associated with a relative risk of 1.20 for all-cause mortality and 1.29 for cardiovascular mortality.²¹ Drug-induced prolongation and its relation to sudden death have made assessment of QT interval responses to new pharmaceutical drugs an important topic for manufacturers and regulatory agencies²² (see Chapter 9).

Other Measures of Ventricular Recovery

QT Dispersion

As noted, the QT interval varies from lead to lead. In normal persons, the QT interval may vary by up to 65 milliseconds among leads (referred to as QT dispersion), and it typically is longest in leads V_2 and V_3 . Increases in the maximum range of intervals has been related to electrical instability and the risk of ventricular arrhythmogenesis, although its practical clinical usefulness remains limited. We concur with the conclusions of the 2009 Joint Society Task Force that "QT dispersion not be included in routine ECG reports. However, because of the fundamental importance of the heterogeneity of myocardial repolarization in the genesis of malignant ventricular arrhythmias, continued research into the identification of markers of increased dispersion of myocardial repolarization on the body surface ECG is encouraged."¹⁸

The QRST Angle. The concordance between the orientation of the normal QRS complex and the normal ST-T wave described earlier can be expressed vectorially. An angle can be visualized in three-dimensional space between the vector representing the mean QRS force and the vector representing the mean ST-T force. This angle is the spatial QRST angle. The angle between the two vectors in the frontal plane represents a reasonable simplification and normally is less than 60 degrees (and usually less than 30 degrees). Abnormalities of the QRST angle reflect abnormal relationships between the properties of activation and recovery.

The clinical significance of an abnormal QRST angle has been long debated. A recent analysis of the Third National Health and Nutrition Survey (NHANES III) reported a significant increase in both all-cause (multivariate hazard ratios of 1.30 to 1.87) and cardiovascular (multivariate hazard ratios of 1.82 to 2.21) mortality over a 14-year period in subjects without clinically evident heart disease but with increased QRST angles.²³

The Ventricular Gradient. If the two vectors representing mean activation and mean recovery forces are added, a third vector known as the *ventricular gradient* is created. This vector represents the net area under the QRST complex. The concept of the ventricular gradient originally was developed to assess the variability that exists in regional repolarization properties; the greater these differences, the larger will be the ventricular gradient. In addition, because changes in activation patterns produced, for example, by bundle branch block cause

FIGURE 12-12 Normal tracing with a juvenile T wave inversion pattern in leads V₁, V₂, and V₃, as well as early repolarization pattern manifested by ST-segment elevation in leads I, II, aVF, V₄, V₅, and V₆. A J point notch is present in lead V₄. (Courtesy Dr. C. C. Fisch.)

corresponding changes in recovery patterns (see later), no change in the ventricular gradient typically results. The ventricular gradient should thus allow a measure of regional recovery properties that is independent of the activation pattern. This measurement has possible although unproven relevance to the genesis of reentrant arrhythmias that may be caused, in part, by abnormal regional variations in refractory periods.

Normal Variants

Numerous variations of these normal ECG patterns occur in subjects without heart disease. These variations are important to recognize because they may be mistaken for significant abnormalities, leading in some cases to erroneous and potentially harmful diagnoses of heart disease.

T waves can be inverted in the right precordial leads in normal persons (Fig. 12-12). T waves commonly are inverted in all precordial leads at birth and usually become upright as time passes. This *persistent juvenile pattern*, with inverted T waves in leads to the left of V₁, occurs in 1% to 3% of adults and is more common in women than in men and more common in African Americans than in other racial or ethnic groups.

The ST segment can be significantly elevated in normal persons, especially in the right and midprecordial leads (Fig. 12-13). ST-segment elevation may appear alone or as part of the *early repolarization* pattern, one of the J wave syndromes referred to earlier. Classic features of this syndrome include upwardly concave ST-segment elevation, tall precordial R waves, distinctive J waves with slurring or notching of the terminal QRS complex, an early R wave transition in the precordial leads, and asymmetric T waves with a gradual upstroke and rapid descent.

This pattern occurs in 1% to 13% of the general population and is most prevalent in young adults, especially African American men and those who are athletically active. Its appearance is labile, being most prominent under conditions of increased vagal tone.

Case reports and case-control^{24,25} and population-based²⁶ studies have documented a significant association of ST-segment elevation plus both J waves and QRS notching with ventricular tachyarrhythmias and sudden cardiac arrest with ventricular fibrillation. Haissaguerre and colleagues²⁴ reported a case-control study in which these patterns were found in 31% of patients with episodes of ventricular fibrillation but in only 5% of those without such episodes. Population-based studies by Tikkanen

and associates²⁶ demonstrated a significantly increased risk of arrhythmic deaths (with adjusted hazard ratios of 1.43 with J point elevation of 0.1 mV or greater and 3.14 with J point elevation above 0.2 mV) among asymptomatic adults with early repolarization patterns characterized by horizontal or downsloping ST segments in the inferior leads (the pattern observed in greater than 70% of the general population with early repolarization patterns); however, subsets of patients with ECG changes in lateral leads or with ascending ST segments in the inferior lead patterns (the pattern observed in approximately 90% of young athletes) had no increased risk. Similarly, otherwise healthy subjects with J point elevation without J waves appear to have no increase in risk of sudden death.²⁵ The identification and significance of benign and potentially malignant variants of early repolarization patterns continue to be a subject of ongoing controversy and study (see Chapter 37).

THE ABNORMAL ELECTROCARDIOGRAM

The prevalence of abnormal ECGs in the general population increases progressively with age. For example, screening ECGs revealed abnormalities requiring follow-up investigation in 2.5% of more than 32,000 high school students,²⁷ whereas abnormal ECGs were recorded in 36% of adults 70 to 79 years of age without overt cardiovascular disease.²⁸ Many of these abnormalities have prognostic as well as diagnostic import; a recent review of reports that included more than 173,000 persons identified high-quality evidence supporting the prognostic value of six ECG abnormalities (ST-segment abnormalities, T wave abnormalities, combined ST-segment and T wave abnormalities, left ventricular hypertrophy [LVH], bundle branch block, and left axis deviation), with relative risk factors for subsequent cardiovascular events of 1.5 to 1.9.²⁹

Atrial Abnormalities

Various pathophysiologic events alter atrial activation to produce abnormal P wave patterns. Three general categories of P wave changes are described here: abnormal patterns of activation and conduction, left atrial abnormalities, and right atrial abnormalities.

Abnormal Atrial Activation and Conduction. Small shifts in the site of initial activation within the SA node or to ectopic sites within

FIGURE 12-13 Normal variant pattern with the "early repolarization" variant of ST-segment elevation. The ST-segment elevation and a J point notch are most marked in the midprecordial lead V₄. Reciprocal ST-segment depression and PR segment depression are absent (except in lead aVR), features that may be helpful in the differential diagnosis of ischemia and pericarditis, respectively. Note also that lead II has a baseline recording shift. (From Goldberger AL, Goldberger ZD, Shvilkin A: *Goldberger's Clinical Electrocardiography: A Simplified Approach*. 8th ed. Philadelphia, Saunders, 2012.)

the atria can lead to major changes in the pattern of atrial activation and, hence, in the morphology of P waves. These shifts can occur as *escape rhythms* if the normal SA nodal pacemaker fails or as *accelerated ectopic rhythms* if the automaticity of an ectopic site is enhanced (see Chapter 37).

P wave patterns may indicate the site of impulse formation and the path of subsequent activation. For example, a negative P wave in lead I suggests activation beginning in the left atrium. Inverted P waves in the inferior leads generally correspond to a posterior atrial activation site. However, the correlations of P wave patterns with the location of origin are highly variable. Accordingly, these patterns may, as a group, be referred to as *ectopic atrial rhythms*, rather than assigned terms that suggest a specific site of origin.

Interatrial block, representing conduction delays between the atria, alters the duration and pattern of P waves.³⁰ When conduction from the right to the left atrium within Bachmann's bundle is delayed, the normal lag in left atrial activation relative to that of the right atrium increases. P wave duration is prolonged beyond 110 milliseconds, and P waves typically have two humps in lead II, with the first representing right atrial and the second reflecting left atrial activation. With more advanced block, the sinus node impulses reach the left atrium only after passing inferiorly to near the atrioventricular junction and then superiorly through the left atrium. In such cases, P waves are wide and biphasic (an initial positive wave followed by a negative deflection) in the inferior leads.

Interatrial block is common, being found in approximately 10% of young adults and in as many as 60% of hospitalized adults. Although often associated with left atrial enlargement, it often is seen as an isolated conduction defect without concomitant structural abnormalities. It is an independent predictor of atrial fibrillation and other supraventricular tachyarrhythmias and commonly is associated with left atrial enlargement, left atrial thrombi, and systemic embolization.

Left Atrial Abnormalities. Anatomic abnormalities of the left atrium that alter the P waves include atrial dilation, atrial muscular hypertrophy, and elevated intra-atrial pressures. Because these pathophysiologic abnormalities commonly coexist and can produce similar ECG effects, the resulting patterns are often referred to as *left atrial abnormalities*.³¹

Mechanisms for the Electrocardiographic Abnormalities. Increases in left atrial mass or chamber size cause increases in P wave amplitude and duration. Because the left atrium is located posteriorly in the chest and is activated relatively late during the P wave, these changes produce prolonged P wave duration, notching of P waves in the inferior leads, and increased amplitude of terminal P wave forces in the right precordial leads.

Diagnostic Criteria. These pathophysiologic changes are reflected in the most commonly used criteria for diagnosing left atrial abnormality listed in Table 12-3 and illustrated in Figures 12-14 and 12-15.

Diagnostic Accuracy. Recent studies correlating these ECG criteria with left atrial volumes determined by three-dimensional computed tomography³² and magnetic resonance imaging³³ have demonstrated the limited value of these criteria. A prolonged P wave duration has a high sensitivity (71% to 84%) but low specificity (35% to 55%). By contrast, bifid P waves and increased negative terminal P wave amplitude in lead V₁ have low sensitivities (8% to 19% and 37% to 49%, respectively) and high specificities (85% to 99% and 54% to 88%, respectively).

Clinical Significance. The ECG features of left atrial abnormality are associated with more severe left ventricular dysfunction in patients with ischemic heart disease (see Chapter 54) and with more severe valve damage in patients with mitral or aortic valve disease (see Chapter 63). Patients with left atrial abnormalities also have a higher-than-normal incidence of atrial tachyarrhythmias, including atrial fibrillation.³⁴

Right Atrial Abnormality. The ECG features of right atrial abnormality are illustrated in Figures 12-14 and 12-15. P wave amplitudes in the limb and right precordial leads typically are abnormally high. In addition, certain QRS patterns also may suggest right atrial abnormalities (see Table 12-3). As in the case of left atrial abnormality, the term *right atrial abnormality* may be used rather than designations such as "right atrial enlargement" that suggest a particular underlying pathophysiology.

FIGURE 12-14 Top, Schematic representation of atrial depolarization. Bottom, P wave patterns associated with normal atrial activation (left) and with right atrial (middle) and left atrial (right) abnormalities. (Modified from Park MK, Guntheroth WG: *How to Read Pediatric ECGs*. 4th ed. St. Louis, Mosby, 1993.)

TABLE 12-3 Common Diagnostic Criteria for Left and Right Atrial Abnormalities

LEFT ATRIAL ABNORMALITY	RIGHT ATRIAL ABNORMALITY
Prolonged P wave duration to >120 msec in lead II	Peaked P waves with amplitudes in lead II to >0.25 mV ("P pulmonale")
Prominent notching of P wave, usually most obvious in lead II, with the interval between notches of >0.40 msec ("P mitrale")	Prominent initial positivity in lead V ₁ or V ₂ >0.15 mV (1.5 mm at usual gain)
Ratio between the duration of the P wave in lead II and duration of the PR segment >1.6	Increased area under initial positive portion of the P wave in lead V ₁ to >0.06 mm-sec
Increased duration and depth of terminal-negative portion of P wave in lead V ₁ (P terminal force) so that area subtended by it >0.04 mm-sec	Rightward shift of mean P wave axis to more than +75 degrees
Leftward shift of mean P wave axis to between -30 and -45 degrees	

*In addition to criteria based on P wave morphologies, right atrial abnormality is suggested by QRS changes including a qR pattern in the right precordial leads without evidence of myocardial infarction (but especially with other signs of RV overload) or low-amplitude (<600 μ V = 6 mm at usual gain) QRS complexes in lead V₁ with a threefold or greater increase in lead V₂.

Bilateral abnormality

FIGURE 12-15 Bilateral abnormality, with tall P waves in lead II (right atrial abnormality) and an abnormally large terminal negative component of the P wave in lead V₁ (left atrial abnormality). The P wave also is notched in lead V₅.

Diagnostic Criteria. Criteria commonly used to diagnose right atrial abnormality are listed in Table 12-3. In addition to criteria based on P wave morphology, right atrial abnormality is suggested by QRS changes, including a qR-type pattern in the right precordial leads without evidence of myocardial infarction (and especially associated with a right ventricular overload pattern) or low-amplitude QRS complexes in lead V₁ together with a threefold or greater increase in lead V₂.

Mechanisms for the Electrocardiographic Abnormalities. Greater right atrial mass generates greater electrical force early during atrial activation, producing taller P waves in limb leads and increasing the initial P wave deflection in leads over the right heart, such as lead V₁. In contrast with left atrial abnormalities, P wave duration is not prolonged.

Diagnostic Accuracy. Imaging studies³³ have shown that the ECG features of right atrial abnormality have limited sensitivity (7% to 10%) but high specificity (96% to 100%) for detecting anatomic right atrial enlargement.

Clinical Significance. Patients with chronic obstructive pulmonary disease and this ECG pattern (often referred to as *P pulmonale*) have more severe pulmonary dysfunction, with significantly reduced survival, than in those with other atrial abnormalities (see Chapter 74). However, comparison of ECG and hemodynamic parameters has not demonstrated a close correlation of P wave patterns and right atrial hypertension.

Other Atrial Abnormalities. Patients with abnormalities in both atria—that is, *bilateral abnormality*—can have ECG patterns reflecting each defect. Suggestive findings include large biphasic P waves in lead V₁ and tall and broad P waves in leads II, III, and aVF (see Fig. 12-15).

Ventricular Hypertrophy

Left Ventricular Hypertrophy

LVH produces changes in the QRS complex, the ST segment, and the T wave. The most characteristic finding is increased amplitude of the QRS complex. R waves in leads facing the left ventricle (i.e., leads I, aVL, V₅, and V₆) are taller than normal, and S waves in leads overlying the opposite side of the heart (i.e., V₁ and V₂) are deeper than normal. These changes are illustrated in Figure 12-16.

Other QRS changes seen in cases of LVH include widening of the QRS complex beyond 110 milliseconds, a delay in the intrinsicoid deflection (ventricular activation time), and notching of the QRS complex. Additional abnormalities may include prolongation of the QT interval and evidence of left atrial abnormality.

ST-T wave patterns vary widely in patients with LVH. The ST segment may be normal or somewhat elevated in leads with tall R waves. In many patients, however, the ST segment is depressed and followed by an inverted T wave (Fig. 12-17). Typically, the ST segment slopes downward from a depressed J point and the T wave is asymmetrically inverted. These LVH-related repolarization changes usually occur in patients with QRS changes but may appear alone. Particularly prominent, inverted T waves (especially in the midprecordial leads) are characteristic of hypertrophic cardiomyopathy with predominant apical thickening (Yamaguchi syndrome) (see Fig. 12-46).

These ECG features are most typical of LVH induced by pressure overload of the left ventricle. Volume overload can produce a somewhat different pattern, including tall upright T waves, and sometimes narrow (less than 25 milliseconds) but deep (0.2 mV or greater) Q

FIGURE 12-16 LVH increases the amplitude of electrical forces directed to the left and posteriorly. In addition, repolarization abnormalities can cause ST-segment depression and T wave inversion in leads with a prominent R wave. RVH can shift the QRS vector to the right, usually with an R, RS, or qR complex in lead V₁, especially when caused by severe pressure overload. T wave inversions may be present in the right precordial leads. (From Goldberger AL, Goldberger ZD, Shvilkin A: *Goldberger's Clinical Electrocardiography: A Simplified Approach*. 8th ed. Philadelphia, Saunders, 2012.)

waves in leads facing the left side of the septum or the left ventricular free wall (Fig. 12-18). These distinctions have limited value in identifying hemodynamic conditions, and their diagnostic use has been discouraged.³¹

Mechanisms for the Electrocardiographic Abnormalities. ECG changes of LVH result from interrelated structural, biochemical, and bioelectric changes.³⁵ Structural components include an increase in the size of activation fronts moving across the thickened wall that generate higher body surface voltages. The longer time required to activate the thickened wall combined with slower-than-normal conduction within the working myocardium also contributes to the high voltage and to QRS prolongation.

At the cellular level, hypertrophy is associated with a form of electrical remodeling. This includes biochemical changes in gap junctions and ion channels that alter charge densities. Bioelectric changes, including changes in fiber diameter and length and changes in myocyte branching patterns, alter impulse propagation. The

FIGURE 12-17 Marked LVH pattern with prominent precordial lead QRS voltages, ST-segment depression, and T wave inversion (compare with Fig. 12-18). Left atrial abnormality also is present.

FIGURE 12-18 LVH pattern with prominent positive anterior T waves on an ECG from a patient with severe aortic regurgitation (sometimes called the left ventricular diastolic or volume overload pattern).

heterogeneous distribution of these abnormalities and intramural scarring associated with hypertrophy may disrupt smooth propagation of wave fronts to produce notching of the QRS complex.

ST-T abnormalities may reflect primary disorders of repolarization that accompany the cellular processes of hypertrophy, or they may reflect subendocardial ischemia caused by high wall tension and limited blood flow to the subendocardium of the thickened wall. Echocardiographic studies have suggested that ST-T abnormalities are associated with reduced endomyocardial radial strain, suggesting subendocardial underperfusion.³⁶

Diagnostic Criteria

Many sets of diagnostic criteria for LVH have been developed based on these ECG abnormalities. Several of the more commonly used criteria are listed in Table 12-4; a comprehensive list of criteria has been presented by Hancock and colleagues.³¹

Most methods assess the presence or absence of LVH as a binary function, indicating that LVH either does or does not exist, based on an empirically determined set of criteria. For example, the Sokolow-Lyon and Cornell voltage criteria require that voltages in specific leads exceed certain values. The Romhilt-Estes point score system assigns point values to amplitude and other criteria, including QRS axis and P wave patterns; definite LVH is diagnosed if a score of 5 points or more is obtained and probable LVH is diagnosed if a score of 4 points is obtained. The Cornell voltage duration method includes measurement of QRS duration as well as amplitudes.

Other methods seek to quantify left ventricular mass as a continuum. Diagnosis of LVH can then be based on a computed mass that exceeds an independently determined threshold. One set of criteria applying this approach is used for the Cornell regression equation shown in Table 12-4.

Diagnostic Accuracy. The relative diagnostic accuracies of these methods are highly variable, differing with the specific criteria tested, the imaging method used to determine anatomic measurements, and the population studied. For example, sensitivities range from approximately 10% in the general population to approximately 50% in cohorts with hypertension.³⁷ Accuracy also varies with sex (with lower ECG voltages in women than in men), with race (with higher voltages in African Americans than in other racial groups), and with body habitus (with reduced voltages associated with obesity).

Most studies have reported low sensitivity and high specificity. One review of 21 studies reported a median sensitivity for six commonly used criteria ranging from 10.5% to 21% and a median specificity of 89% to 99%.³⁸ Accuracies tend to be higher for the Cornell voltage, voltage duration, and regression

methods than for other criteria. For example, one study based on computed tomographic measures of ventricular size reported sensitivities of 4% to 46% and specificities of 90% to 97% for the common LVH criteria; the Cornell voltage criterion that had the highest overall accuracy of 92%.³⁹ The low sensitivities limit the value of these criteria as screening tools in the general population. Because of the variability in the accuracy of the criteria from one trial to another, no one criterion can be established as the preferred method.³¹

Limited accuracy may reflect a limited relationship between the structural changes of LVH and the associated electrophysiologic consequences. For example, electrical remodeling associated with anatomic LVH may reduce transmembrane ion flows to decrease rather than increase ECG voltages.³⁵ Also, accuracy may be reduced by the effects of other abnormalities such as conduction defects and myocardial infarction, as discussed later. Repolarization abnormalities associated with QRS findings are associated with a threefold greater prevalence of anatomic LVH in patients without coronary artery disease.

TABLE 12-4 Common Diagnostic Criteria for Left Ventricular Hypertrophy

MEASUREMENT	CRITERIA
Sokolow-Lyon voltages	$SV_1 + RV_5 > 3.5$ mV $RaVL > 1.1$ mV
Romhilt-Estes point score system*	Any limb lead R wave or S wave > 2.0 mV (3 points) or SV_1 or $SV_2 \geq 3.0$ mV (3 points) or RV_5 to $RV_6 \geq 3.0$ mV (3 points) ST-T wave abnormality, no digitalis therapy (3 points) ST-T wave abnormality, digitalis therapy (1 point) Left atrial abnormality (3 points) Left axis deviation ≥ -30 degrees (2 points) QRS duration ≥ 90 msec (1 point) Intrinsicoid deflection in V_5 or $V_6 \geq 50$ msec (1 point)
Cornell voltage criteria	$SV_3 + RaVL \geq 2.8$ mV (for men) $SV_3 + RaVL > 2.0$ mV (for women)
Cornell regression equation	Risk of LVH = $1/(1 + e^{-\text{exp}})^{\dagger}$
Cornell voltage duration measurement	QRS duration \times Cornell voltage > 2436 mm-sec [‡] QRS duration \times sum of voltages in all leads > 1742 mm-sec

PTF = P terminal force; PTFV₁ = P terminal force in lead V₁.

*Probable LVH is diagnosed with totals of 4 points, and definite LVH is diagnosed with totals of 5 or more points.

[†]For subjects in sinus rhythm, $\text{exp} = 4.558 - 0.092 (SV_3 + RaVL) - 0.306 TV_1 - 0.212 QRS - 0.278 PTFV_1 - 0.559$ (sex). Voltages are in mV, QRS is QRS duration in milliseconds, PTF is the area under the P terminal force in lead V₁ (in mm-sec), and sex = 1 for men and 2 for women. LVH is diagnosed as present if $\text{exp} < -1.55$.

[‡]For women, add 8 mm.

Clinical Significance

An accurate ECG diagnosis of LVH is important to detect hypertrophy, assess prognosis, and monitor progression or regression of hypertrophy during treatment. Although imaging methods may provide a more direct assessment of structural LVH, ECG findings may provide independent, clinically important information concerning the electrical changes resulting from hypertrophy that reflect the underlying cellular abnormalities with a potential impact on prognosis.³⁵

The presence of ECG criteria for LVH identifies a subset of the general population, and of those with hypertension, with a significantly increased risk for cardiovascular morbidity and mortality. For example, the Losartan Intervention for Endpoint Reduction in Hypertension (LIFE) study⁴⁰ demonstrated that lower Cornell and Sokolow-Lyon voltages during antihypertensive therapy in patients with systolic hypertension correlate with lower likelihood of cardiovascular mortality and morbidity independent of the extent of blood pressure lowering. A 1 standard deviation decrease in the Cornell product was associated with a 25% decrease in cardiovascular deaths and a 17% lower rate of myocardial infarction.

Patients with repolarization abnormalities have, on average, more severe degrees of anatomic LVH and a greater risk of future cardiovascular events. In the LIFE study, the development of new ST-T wave abnormalities in hypertensive patients with LVH on antihypertensive therapy was associated with significant increases in the risk of cardiovascular death (hazard ratio, 2.42) and myocardial infarction (hazard ratio, 1.95).⁴¹

Right Ventricular Hypertrophy

Right ventricular hypertrophy (RVH) changes the ECG in fundamental ways, whereas an enlarged left ventricle produces predominantly quantitative changes in underlying normal waveforms. The ECG changes associated with moderate to severe concentric RVH most

TABLE 12-5 Common Diagnostic Criteria for Right Ventricular Hypertrophy

R in V ₁ ≥ 0.7 mV
QR in V ₁
R/S in V ₁ > 1 with R > 0.5 mV
R/S in V ₅ or V ₆ < 1
S in V ₅ or V ₆ > 0.7 mV
R in V ₅ or V ₆ ≥ 0.4 mV with S in V ₁ ≤ 0.2 mV
Right axis deviation (> 90 degrees)
S ₁ Q ₃ pattern
S ₁ S ₂ S ₃ pattern
P pulmonale

From Murphy ML, Thenabadu PN, de Soyza N, et al: Reevaluation of electrocardiographic criteria for left, right and combined cardiac ventricular hypertrophy. *Am J Cardiol* 53:1140, 1984.

commonly include abnormal, tall R waves in anteriorly and rightward-directed leads (leads aVR, V₁, and V₂), and deep S waves and abnormally small r waves in leftward-directed leads (I, aVL, and lateral precordial leads) (Fig. 12-19). These changes result in a reversal of normal R wave progression in the precordial leads, a shift in the frontal plane QRS axis to the right, and the presence of S waves in leads I, II, and III (the S₁S₂S₃ pattern).

Less severe hypertrophy, especially when limited to the outflow tract of the right ventricle that is activated late during the QRS complex, produces less marked changes. Abnormalities may be limited to an rSr' pattern in V₁ and persistence of s (or S) waves in the left precordial leads. This pattern is typical of right ventricular volume overload such as that produced by an atrial septal defect.

Diagnostic Criteria

Commonly relied-on criteria for the ECG diagnosis of RVH are listed in Table 12-5.

Diagnostic Accuracy. The diagnostic accuracies of these criteria remain unclear. Although the older literature has suggested very high specificities for many of the listed criteria, these estimates often were based on small and highly selective populations. The sensitivities and specificities in the general population remain to be accurately determined.

Mechanisms for the Electrocardiographic Abnormalities. As in LVH, RVH increases current fluxes between hypertrophied cells and the size of activation fronts moving through the enlarged right ventricle to produce higher-than-normal voltages on the body surface. The normal right ventricle is considerably smaller than the left ventricle and produces electrical forces that are largely canceled by those generated by the larger left ventricle. Thus, for RVH to be manifested on the ECG, it must be severe enough to overcome the masking effects of the larger left ventricular forces.

In addition, the activation time of the right ventricle is prolonged. Right ventricular activation now ends after activation of the left ventricle is completed, so that the forces generated by the right ventricle are no longer canceled by the more powerful forces of the left ventricle and become manifest late in the QRS complex (e.g., the generation of S waves). Because the right ventricle is located anteriorly and to the right of the left ventricle, RVH produces increased potentials in leads directed anteriorly and to the right, that is, in the right precordial leads.

Clinical Significance

Chronic obstructive pulmonary disease (see Chapter 74) can induce ECG changes by producing RVH, changing the position of the heart within the chest, and hyperinflating the lungs (Fig. 12-20). QRS changes caused by the insulating and positional changes produced by hyperinflation of the lungs include reduced amplitude of the QRS complex, right axis deviation in the frontal plane, and delayed transition in the precordial leads. Evidence of true RVH includes (1) right axis deviation more positive than 110 degrees; (2) deep S waves in the lateral precordial leads; and (3) an S₁Q₃T₃ pattern, with an S wave in lead I (as an RS or rS complex), an abnormal Q wave in lead III, and an inverted T wave in the inferior leads.

The ECG evidence of RVH has limited value in assessing the severity of pulmonary hypertension or lung disease. QRS changes generally do not appear until ventilatory function is significantly depressed, with the earliest change commonly being a rightward shift in the mean QRS axis, and the correlation with ventilatory function or hemodynamics is poor.

Pulmonary embolism causing acute right ventricular pressure overload may generate characteristic ECG patterns (**Fig. 12-21**) (see **Chapter 73**). These include (1) a QR or qR pattern in the right ventricular leads; (2) an $S_1Q_3T_3$ pattern; (3) ST-segment deviation and T wave inversions in leads V_1 to V_3 ; and (4) incomplete or complete

right bundle branch block (RBBB). Sinus tachycardia usually is present. Occasionally, with massive pulmonary arterial obstruction, ST-segment elevations may be seen in the right midprecordial leads.

Even with major pulmonary artery obstruction, however, the ECG may show little more than minor or nonspecific waveform changes or may be normal in appearance. The classic $S_1Q_3T_3$ pattern occurs in only approximately 10% of cases of acute pulmonary embolism (see **Chapter 73**). Furthermore, the specificity of this finding is limited, because it can occur with other causes of pulmonary hypertension or as a normal variant. An analysis of the ECGs of patients with right ventricular dilation caused by acute pulmonary embolism found positive predictive accuracies of 23% to 69%.⁴²

FIGURE 12-19 RVH pattern most consistent with severe pressure overload of the right ventricle. Findings include (1) a tall R wave in V_1 (as part of the qR complex), (2) right axis deviation, (3) T wave inversion in V_1 through V_3 , (4) delayed precordial transition zone (rS in V_6), (5) right atrial abnormality, and (6) an $S_1Q_3T_3$ pattern.

Biventricular Hypertrophy

Hypertrophy of both ventricles produces complex ECG patterns. In contrast with biatrial enlargement, the result is not the simple sum of the two sets of abnormalities. The effects of enlargement of one chamber may cancel the effects of enlargement of the other. The greater left ventricular forces generated in LVH increases the degree of RVH needed to overcome the dominance of the left ventricle, and the anterior forces produced by RVH may cancel the enhanced posterior forces generated by LVH.

Because of these factors, specific ECG criteria for either RVH or LVH are seldom observed with biventricular enlargement. Rather, ECG patterns usually are a modification of the features of LVH, such as (1) tall R waves in the right and left precordial leads, (2) vertical heart position or right axis deviation, (3) deep S waves in the left precordial leads,

FIGURE 12-20 Pulmonary emphysema simulating anterior infarction in a 58-year-old man with no clinical evidence of coronary disease. In the ECG tracing in **A**, note the loss of anterior R waves in the precordial leads; relative normalization of R wave progression occurs with placement of the chest leads an interspace below their usual position (e.g., $*V_1$, $*V_2$), as shown in **B**. (Modified from Chou TC: *Pseudo-infarction (noninfarction Q waves)*. In Fisch C [ed]: *Complex Electrocardiography*. Vol 1. Philadelphia, FA Davis, 1973.)

FIGURE 12-21 Acute cor pulmonale secondary to pulmonary embolism simulating inferior and anterior infarction. This tracing exemplifies the classic pseudoinfarction patterns sometimes seen with an $S_1Q_3T_3$ pattern, a QR in lead V_1 with poor R wave progression in the right precordial leads (clockwise rotation), and right precordial to midprecordial T wave inversion (V_1 to V_4). (From Goldberger AL, Goldberger ZD, Shvilkin A: *Goldberger's Clinical Electrocardiography: A Simplified Approach*. 8th ed. Philadelphia, Saunders, 2012.)

FIGURE 12-22 ECG from a 45 year-old woman with severe mitral stenosis showing multiple abnormalities. The rhythm is sinus tachycardia. Right axis deviation and a tall R wave in lead V_1 are consistent with RVH. The very prominent biphasic P wave in lead V_1 indicates left atrial abnormality. The tall P waves in lead II suggest concomitant right atrial abnormality. Nonspecific ST-T changes and incomplete RBBB also are present. The combination of RVH and marked left or biatrial abnormality is highly suggestive of mitral stenosis. (From Goldberger AL, Goldberger ZD, Shvilkin A: *Goldberger's Clinical Electrocardiography: A Simplified Approach*. 8th ed. Philadelphia, Saunders, 2012.)

or (4) a shift in the precordial transition zone to the left—all with evidence of LVH. The presence of prominent left atrial abnormality or atrial fibrillation with evidence of right ventricular or biventricular enlargement (especially LVH with a vertical or rightward QRS axis) should suggest chronic rheumatic valvular disease (Fig. 12-22) (see Chapter 63).

Intraventricular Conduction Delays

Intraventricular conduction delays change the shape and duration of the QRS complex. These patterns may result from abnormalities in the specialized conducting tissues of the atria or ventricles or in cardiac muscle. They may be permanent, caused, for example, by scarring, or they may be transient, related to functional abnormalities in conduction.⁴³

Fascicular Block

Absolute or relative delays in conduction in one fascicle of the left bundle system, fascicular block, result in an abnormal sequence of early left ventricular activation, leading to characteristic ECG patterns.⁴⁴ Even modest delays in conduction may be enough to alter ventricular activation patterns sufficiently to produce characteristic ECG patterns; a complete block of conduction is not required.

Left Anterior Fascicular Block

The ECG features of left anterior fascicular block (LAFB) are listed in Table 12-6 and illustrated in Figure 12-23. The most

characteristic finding is marked left axis deviation.

The left anterior fascicle normally activates the uppermost portion of the septum, the anterosuperior portion of the left ventricle, and the left anterior papillary muscle early during the QRS complex. With LAFB, these regions are activated later than normal, resulting in unbalanced inferior and posterior forces early during ventricular activation (activated normally by the left posterior fascicle) and unopposed anterosuperior forces later during the QRS complex (the region activated late).

These changes are manifested on the ECG as a leftward shift of the mean frontal plane QRS axis to between -45 and -90 degrees. Lesser degrees of block may cause shifts of the mean axis from previous values toward the left without exceeding the normal limits.⁴⁴

The characteristic pattern in the inferior leads includes initial r waves (caused by early unopposed activation of the inferoposterior left ventricle) followed by deep S waves (caused by late unopposed activation of the anterosuperior left ventricle), leading to left axis deviation with rS patterns in leads II, III, and aVF. The left-looking leads (e.g., leads I, aVL, V_5 , and V_6) show small q waves and qR patterns.

LAFB also can produce prominent changes in the precordial leads. Leads V_4 through V_6 commonly show deep S waves, that is, the pattern of delayed transition, produced by the late activation of the anterosuperior left ventricle. In some cases, q waves may appear in the right precordial leads that normalize if the electrodes are placed one interspace lower than usual. The overall QRS duration is not prolonged; fascicular block alters the sequence but not the overall duration of left ventricular activation.

LAFB probably is the most common cause of left axis deviation, although it is not synonymous with it. Axis shifts to between -30 and -45 degrees commonly reflect other conditions, such as LVH, without conduction system damage.

Damage to the left anterior fascicle is very common because of the delicate nature of the structure. LAFB is common in persons without overt cardiac disease and in a variety of cardiac conditions. Some evidence indicates that this finding has a negative impact on prognosis or on progression of conduction system disease; a review in support of U.S. Preventive Services Task Force²⁹ (USPSTF) data reported a pooled adjusted hazard ratio for mortality of 1.5 based on three studies.

LAFB can mask or mimic ECG changes from other conditions. The development of rS complexes in leads II, III, and aVF can mask the Q waves of an inferior myocardial infarction. The larger R waves in leads

FIGURE 12-23 Diagrammatic representation of fascicular blocks in the left ventricle. **Left**, Interruption of the left anterior fascicle or division (here labeled LAD) results in an initial inferior (1) followed by a dominant superior (2) direction of activation. **Right**, Interruption of the left posterior fascicle or division (here labeled LPD) results in an initial superior (1) followed by a dominant inferior (2) direction of activation. AVN = atrioventricular node; HB = His bundle; LB = left bundle; RB = right bundle. (Courtesy Dr. C. Fisch.)

TABLE 12-6 Common Diagnostic Criteria for Fascicular Blocks

Left Anterior Fascicular Block
Frontal plane mean QRS axis between -45 and -90 degrees
qR pattern in lead aVL
QRS duration <120 msec
Time to peak R wave in aVL ≥ 45 msec
Left Posterior Fascicular Block
Frontal plane mean QRS axis between $+90$ and $+180$ degrees
rS pattern in leads I and aVL with qR patterns in leads III and aVF
QRS duration <120 msec
Exclusion of other factors causing right axis deviation (e.g., right ventricular overload patterns, lateral infarction)

I and aVL and smaller R waves but deeper S waves in leads V_5 and V_6 also make LVH criteria relying on R wave amplitude less valuable.

Left Posterior Fascicular Block

Damage to the left posterior fascicle is less common than injury in the anterior fascicle because of its thicker structure and more protected location near the left ventricular inflow tract. Conduction delay results in early unopposed activation of the anterosuperior left ventricular free wall, followed by late activation of the inferoposterior aspect of the left ventricle—that is, the reverse of the pattern observed with LAFB. This entity is termed *left posterior fascicular block* (LPFB).

The ECG features of LPFB (see Table 12-6 and Fig. 12-23) reflect this altered activation pattern. Right axis deviation, with rS patterns in leads I and aVL as well as qR complexes in the inferior leads, is the result of early unopposed activation forces from the anterosuperior aspect of the left ventricle (activated early via the left anterior fascicle and producing the initial q and r waves) and of late unopposed forces from the inferoposterior free wall (activated late via the left posterior fascicle and generating the late S and R waves). As in the case of LAFB, the overall activation time of the ventricles is not prolonged and the QRS duration remains normal.

LPFB can occur in patients with any cardiac disease but is unusual in otherwise healthy persons. Other conditions that augment the rightward electrical forces in the frontal plane, such as right ventricular overload syndromes and extensive high or anterolateral infarction, can

produce similar ECG patterns. Thus a specific diagnosis of LPFB requires first excluding other causes of right axis deviation. LPFB rarely appears as an isolated finding and most commonly is seen in conjunction with RBBB.

Other Forms of Fascicular Block

Approximately two thirds of people have an anatomic third branch of the left bundle system—the left median or septal fascicle. ECG patterns that suggest left septal or median fascicular block include the absence of septal q waves. It has been recommended, however, that this term not be used in clinical diagnosis, because clear diagnostic criteria have not been developed.⁴³

Left Bundle Branch Block

Left bundle branch block (LBBB) results from conduction delay or block in any of several sites in the intraventricular conduction system, including the main left bundle branch, each of the two major fascicles, the distal conduction system of the left ventricle, and the fibers of the bundle of His that become the main left

bundle branch, or in the ventricular myocardium.

ELECTROCARDIOGRAPHIC ABNORMALITIES. LBBB causes extensive reorganization of the activation and recovery patterns of the left ventricle to produce a widened QRS complex with characteristic changes in the shape of the QRS complex and ST-T wave (Fig. 12-24). Commonly accepted diagnostic criteria for LBBB are listed in Table 12-7. Basic requirements include QRS duration of 120

FIGURE 12-24 Comparison of typical QRS-T patterns in RBBB and LBBB with the normal pattern in leads V_1 and V_6 . Note the secondary T wave inversions (arrows) in leads with an rSR' complex with RBBB and in leads with a wide R wave with LBBB. (From Goldberger AL, Goldberger ZD, Shvilkin A: *Goldberger's Clinical Electrocardiography: A Simplified Approach*. 8th ed. Philadelphia, Saunders, 2012.)

TABLE 12-7 Common Diagnostic Criteria for Bundle Branch Blocks

Complete Left Bundle Branch Block
QRS duration ≥ 120 msec
Broad, notched, or slurred R waves in leads I, aVL, V ₅ , and V ₆
Small or absent initial r waves in right precordial leads (V ₁ and V ₂) followed by deep S waves
Absent septal q waves in leads I, V ₅ , and V ₆
Prolonged time to peak R wave (>60 msec) in V ₅ and V ₆
Complete Right Bundle Branch Block
QRS duration ≥ 120 msec
rsr', rsR', or rSR' patterns in leads V ₁ and V ₂
S waves in leads I and V ₆ ≥ 40 msec wide
Normal time to peak R wave in leads V ₅ and V ₆ but >50 msec in V ₁

milliseconds or more; tall, broad, and commonly notched R waves in leads I and aVL and the left precordial leads; narrow r waves followed by deep S waves in the right precordial leads; and, in most cases, absence of septal q waves. The mean QRS axis can be normal, deviated to the left, or rarely, deviated to the right. In addition to these features, some criteria require a prolonged time to the peak of the R wave (≥ 60 milliseconds) in the left precordial leads to diagnose LBBB.⁴³

ST-T wave changes are prominent with LBBB. In most cases, the ST segment and T wave are discordant with the QRS complex. That is, the ST segment is depressed and the T wave is inverted in leads with positive QRS waves (e.g., leads I, aVL, V₅, and V₆), and the ST segment is elevated and the T wave is upright in leads with predominantly negative QRS complexes (e.g., leads V₁ and V₂).

An incomplete form of LBBB may result from lesser degrees of conduction delay in the left bundle branch system. Features of *incomplete LBBB* include modest prolongation of the QRS complex (to between 100 and 119 milliseconds); loss of septal q waves; slurring and notching of the upstroke of tall R waves; and delay in time to peak of the R wave in left precordial leads. The pattern commonly is similar to that of LVH.

Mechanisms for the Electrocardiographic Abnormalities. The LBBB pattern results from an almost completely reorganized pattern of left ventricular activation.⁴⁵ Initial septal activation with LBBB typically occurs on the right (rather than on the left) septal surface, leading to right to left (rather than left to right) activation of the septum, so that normal septal q waves are absent. Left ventricular activation then typically begins on the left septal surface, with a delay of 40 milliseconds or longer caused by slow transseptal spread from the right ventricular side of the septum.

In a significant minority of cases, earliest septal activation occurs in the left midseptal region in or just anterior to the left posterior fascicle, suggesting activation by the left bundle system rather than by transseptal spread. This finding may reflect damage to the left bundle system distal to the initial fibers penetrating the left side of septum or primarily intramuscular conduction delay within the ventricular myocardium.⁴⁶ In such cases, septal q waves may persist.

The subsequent activation of the ventricular free wall is highly variable, depending on the type, location, and extent of the underlying cardiac disease. Spread is disrupted by regions of block in the anterior, inferior, or lateral regions of the left ventricle, forcing activation to maneuver around the block to activate the more distal portions of the ventricle. Most commonly, the region of block is located anteriorly, and the lateral and posterolateral portions of the left ventricle are activated by wave fronts moving around the apex and across the inferior wall in a U-shaped pattern. Irregular spread predominantly through working muscle fibers rather than the specialized conduction system results in notching and slurring of the wide QRS complex. Overall activation may then require more than 180 milliseconds, depending on the functional status of the distal left bundle and Purkinje systems and on the speed of propagation through working cardiac muscle; activation of portions of the left ventricle may not occur until well beyond the end of the QRS complex.⁴⁷

The discordant ST-T wave pattern is a reflection of the altered pattern of ventricular activation. With LBBB, the right ventricle is activated and recovers earlier than the left, so recovery vectors are directed toward the right and away from the left ventricle. Hence positive ST-T waves will be registered in leads over the right ventricle that show S waves and negative ones over the left ventricle with prominent R waves. These ST-T wave changes are referred to secondary ST-T abnormalities because they are generated by abnormalities in conduction; as discussed later, ST-T wave changes produced by direct abnormalities of the recovery process are referred to as primary ST-T abnormalities.

CLINICAL SIGNIFICANCE. LBBB occurs in fewer than 1% of the general population but in more than one third of patients with heart failure, and as many as 70% of persons in whom LBBB develops have preceding ECG evidence of LVH. However, approximately 10% of patients with LBBB have no clinically demonstrable heart disease.

LBBB has significant prognostic implications. In persons with or without overt heart disease, LBBB is associated with a higher-than-normal risk of mortality and morbidity from infarction, heart failure, and arrhythmias including high-grade atrioventricular block. In a recent population-based study, LBBB was significantly related to an increase in sudden death (with a relative risk of 2.7), although not to increased cardiovascular or all-cause mortality.⁴⁸ Among patients with coronary artery disease, including acute myocardial infarction, the presence of LBBB correlates with more extensive disease, more severe left ventricular dysfunction, and reduced survival rates.

Patients with associated left or right axis deviation have more severe clinical manifestations. Left axis deviation is associated with more severe conduction system disease that involves the fascicles and the main left bundle, whereas right axis deviation suggests dilated cardiomyopathy with biventricular enlargement.

The abnormal ventricular activation pattern of LBBB itself induces hemodynamic changes that are superimposed on the abnormalities caused by the underlying heart disease. Whereas normal left ventricular contraction is highly synchronized and begins in all sites within 40 milliseconds, the pattern with LBBB is less coordinated and requires much more time. The result is asynchronous and prolonged left ventricular contraction that results in regional differences in workload caused by abnormal timing and sequences of activation; regional changes in blood flow and metabolism; structural remodeling; and functional mitral valve dysfunction with mitral regurgitation resulting from the altered geometry of the mitral valve apparatus from the changes in activation and contraction patterns.⁴⁹ As a result, cardiac efficiency is reduced. Severe left ventricular dyssynchrony, with a delay of more than 60 milliseconds between septal and lateral wall contraction, is common, with QRS durations of 120 to 150 milliseconds and increases in prevalence as the QRS duration increases (see Chapters 26 and 35).

A major impact of LBBB lies in obscuring or simulating other ECG patterns. The diagnosis of LVH is complicated by the increased QRS amplitude intrinsic to LBBB. In addition, the very high prevalence of anatomic LVH in patients with LBBB makes defining criteria with high specificity difficult. The diagnosis of myocardial infarction may be obscured; as described further on, the emergence of abnormal Q waves with infarction is dependent on a normal initial sequence of ventricular activation, which is absent with LBBB. In addition, ECG patterns of LBBB, including low R wave amplitude in the midprecordial leads and ST-T wave changes, can mimic anterior infarct patterns.

The diffuse ST-T wave abnormalities associated with LBBB also render detection of ischemia at rest and on standard exercise testing unreliable. This clinical problem is compounded by the frequent recording of reversible myocardial perfusion defects in the septal and anteroseptal left ventricle during exercise stress testing in the absence of significant disease of the left coronary system (see Chapter 13). As many as 60% of such findings in patients with LBBB constitute false-positive results and reflect functional abnormalities in regional myocardial blood flow, rather than ischemia related to fixed coronary artery lesions.

Right Bundle Branch Block

RBBB is a result of conduction delay in any portion of the right-sided intraventricular conduction system. The delay is most common in the

main right bundle branch itself and may occur in the bundle of His or in the distal right ventricular conduction system, as after a right ventriculotomy, for example, to correct the tetralogy of Fallot.

ELECTROCARDIOGRAPHIC ABNORMALITIES. Major features of RBBB are illustrated in Figure 12-24, and commonly used diagnostic criteria are listed in Table 12-7. As with LBBB, the QRS complex duration exceeds 120 milliseconds. The right precordial leads show prominent and notched R waves with rsR', or rSR' patterns, whereas leads I and aVL and the left precordial leads demonstrate S waves that are wider than the preceding R wave. The ST-T waves are, as in LBBB, discordant with the QRS complex, so that T waves are inverted in the right precordial leads and upright in the left precordial leads and in leads I and aVL.

The mean QRS axis is not altered by RBBB. Axis shifts can occur, however, as a result of the simultaneous occurrence of fascicular block along with RBBB (see later).

Incomplete RBBB, produced by lesser delays in conduction in the right bundle branch system, is characterized by an rSR' pattern in lead V₁ with a QRS duration between 100 and 120 milliseconds. These changes also may be caused by RVH (especially with a rightward QRS axis) without intrinsic dysfunction of the conduction system. An rSR' morphology in lead V₁ (and sometimes V₂) with a narrow QRS duration (≤ 100 milliseconds) is a common physiologic or positional variant and may normalize when the right precordial electrodes are placed one interspace lower than usual.

MECHANISMS FOR ELECTROCARDIOGRAPHIC ABNORMALITIES. With delay or block in the proximal right bundle branch system, activation of the right side of the septum is initiated only after slow transseptal spread of activation from the left septal surface.⁴⁹ The right ventricular anterior free wall is then excited slowly, followed by activation of the lateral right ventricular wall and, finally, the right ventricular outflow tract.

The result is delayed and slowed activation of the right ventricle. Much or all of the right ventricle undergoes activation after depolarization of the left ventricle has been completed. This reduces the cancellation of right ventricular activation forces by the more powerful left ventricular activation forces. The late and unopposed emergence of right ventricular forces then produces increased anterior and rightward voltage in the later half of the ECG, as well as a prolonged QRS complex.

Discordant ST-T wave patterns are generated by the same mechanisms as for LBBB. With RBBB, recovery forces are directed away from the right and toward the earlier activated left ventricle. The result is inverted T waves in the right precordial leads and positive ones in the left precordial leads.

A substantial proportion of patients with RBBB, especially those with markedly increased QRS durations, exhibit abnormalities of left ventricular activation that are similar to those in patients with LBBB.⁴⁹ This correspondence suggests that many patients with RBBB have diffuse, biventricular conduction system disease.

CLINICAL SIGNIFICANCE. RBBB is a common finding in the general population, and many persons with RBBB have no clinical evidence of structural heart disease. The high prevalence of RBBB corresponds to the relative fragility of the right bundle branch, as suggested by the development of RBBB after the minor trauma produced by right ventricular catheterization.

In patients with no manifest cardiac disease, RBBB generally is

not associated with an increase in risk of cardiac morbidity or mortality,⁴⁸ although right ventricular dilation and reduced function may be present.⁵⁰ When cardiac disease is present, the coexistence of RBBB suggests advanced disease with, for example, more extensive multivessel disease and reduced long-term survival in patients with ischemic heart disease. An entity known as the *Brugada syndrome* has been described, in which an RBBB-like pattern (sometimes called a "pseudo-RBBB pattern") with persistent ST-segment elevation in the right precordial leads is associated with susceptibility to ventricular tachyarrhythmias and sudden cardiac death (see Chapters 32 and 37).

RBBB interferes with other ECG diagnoses, although to a lesser extent than for LBBB. The diagnosis of RVH is more difficult to make with RBBB because of the accentuated positive potentials in lead V₁. RVH is suggested, although with limited accuracy, by the presence of an R wave in lead V₁ that exceeds 1.5 mV and a rightward shift of the mean QRS axis.

The usual criteria for LVH can be applied but have lower sensitivities than with normal conduction. The delay in right ventricular activation that occurs with RBBB increases the cancellation of left ventricular forces during the middle of the QRS complex and reduces the amplitude of the S wave in the right precordial leads and of the R waves in the left precordial leads, thus reducing the accuracy of ECG criteria for LVH. The combination of left atrial abnormality or left axis deviation with RBBB also suggests underlying LVH. Ventricular dyssynchrony also occurs with RBBB but to a lesser extent than with LBBB.

Multifascicular Blocks

The term *multifascicular block* refers to conduction delay or block in more than one of the structural components of the specialized conduction system. Conduction delay in any two components is called *bifascicular block*, and delay in all three fascicles is termed *trifascicular block*. The term *bilateral bundle branch block* has been used to refer to concomitant conduction abnormalities in both the left and right bundle branch systems. As described later on, these terms do not specifically identify sites of conduction delay.

Bifascicular block can have several forms, including RBBB with LAFB, characterized by RBBB plus left axis deviation beyond -45 degrees (Fig. 12-25); RBBB with LPFB, with a pattern of RBBB and a mean QRS axis deviation to the right of $+120$ degrees (Fig. 12-26); and LBBB alone, which may be caused by delay in both the anterior and posterior fascicles. This form of LBBB represents one of the inadequacies

FIGURE 12-25 Sinus rhythm at 95 beats/minute with 2:1 atrioventricular block. Conducted ventricular beats show a pattern consistent with bifascicular block with delay or block in the right bundle and left anterior fascicle.

FIGURE 12-26 Sinus rhythm with a 2:1 atrioventricular block. QRS morphology in the conducted beats is consistent with bifascicular block with delay or block in the right bundle and left posterior fascicle. Subsequently, complete heart block was noted.

of current ECG terminology. The electrophysiologic consequences of these abnormalities are discussed in [Chapters 35 and 36](#).

Trifascicular block involves conduction delay in the right bundle branch plus delay in either the main left bundle branch or in both the left anterior and the left posterior fascicles. The resulting ECG pattern may be that of RBBB or LBBB without or without axis deviation, depending on the relative degree of delay in the affected structures. Ventricular activation begins at the site of insertion of the branch with the fastest conduction time and spreads from there to the remainder of the ventricles. For example, if conduction delay in the right bundle branch exists and the delay in the left bundle branches is less than the delay in the right bundle branch, activation will begin in the right ventricle, and the QRS pattern will resemble that of LBBB. If the delay is greater in the right bundle branch than in the left bundle branch, the ECG pattern will be that of RBBB. The fascicle with the longest delay can vary with, for example, the heart rate, leading to changing or alternating conduction patterns ([Fig. 12-27](#)).

What distinguishes trifascicular block from bifascicular block is an increase in the overall conduction time from the atrioventricular node to the ventricles. In bifascicular block, conduction time through the unaffected fascicle (and hence minimum conduction time) is normal and conduction time from the atrioventricular node to ventricular muscle is normal; accordingly, the PR interval will be normal (in the absence of atrioventricular nodal conduction delay). In trifascicular block, however, the delay in conduction through even the least affected fascicle is abnormally prolonged, so the conduction time from the atrioventricular node to the ventricular myocardium also is prolonged. (Note that only delay, not block, of conduction is required. If complete block were present in all fascicles, conduction would fail and complete heart block would result. This situation is perhaps best illustrated by alternating bundle branch block [see [Fig. 12-27](#)]: If the block were total in one bundle branch, development of block in the other would produce complete atrioventricular block, rather than a change in bundle branch block patterns.) Thus a diagnosis of trifascicular block

requires an ECG pattern of bifascicular block plus evidence of prolonged conduction below the atrioventricular node.

This delay in conduction is most specifically observed as a prolongation of the His-ventricular (HV) time in intracardiac recordings (see [Chapter 33](#)). On the surface ECG, the delay in conduction may be manifested as a prolonged PR interval. However, the PR interval includes conduction time in both the atrioventricular node and in the intraventricular conduction system. Prolonged intraventricular conduction may be insufficient to extend the PR interval beyond normal limits, whereas a prolonged PR interval most commonly reflects delay in the atrioventricular node, rather than in all three intraventricular fascicles. Thus the finding of a prolonged PR interval in the presence of an ECG pattern consistent with bifascicular block is not diagnostic of trifascicular block, whereas the presence of a normal PR interval does not exclude this finding.

The major clinical implication of a multifascicular block is its relation to advanced conduction system disease. It may be a marker for severe myocardial disease and may identify patients at risk for heart block (see [Figs. 12-25 and 12-26](#)), as discussed in [Chapters 36 and 37](#).

Rate-Dependent Conduction Blocks

Intraventricular conduction delays can result from the effects of changes in the heart rate. *Rate-dependent block*, usually in the form

FIGURE 12-27 Multifascicular block manifested by alternating bundle branch blocks and PR intervals (sections A-C), recorded on separate days. A, Lead V1 recording shows a RBBB with a prolonged PR interval of 280 msec. B, Lead V1 shows LBBB with a PR of 180 msec. C, Leads I, II, III and V1 show alternating RBBB and LBBB patterns, along with PR alternation. The limb leads also show left anterior fascicular block (with subtle alternation of the QRS morphology). Alternating bundle branch block of this type is consistent with trifascicular conduction pathology. (From Fisch C: *Electrocardiography of Arrhythmias*. Philadelphia, Lea & Febiger, 1990.)

FIGURE 12-28 Atrial tachycardia with a type I second-degree atrioventricular block, ventricular aberration resulting from the Ashman phenomenon, and probably concealed transseptal (retrograde) conduction. **Top.** On the ECG tracing, the long pause of the atrial tachycardia is followed by five QRS complexes with RBBB morphology. The RBBB of the first QRS reflects the Ashman phenomenon. The aberration is perpetuated by concealed transseptal activation from the left bundle (LB) into the right bundle (RB), with block of antero-grade conduction of the subsequent sinus impulse in the RB. Foreshortening of the R-R cycle, a manifestation of the Wenckebach structure, disturbs the relationship between transseptal and antero-grade sinus conduction, and RB conduction is normalized. **Bottom.** In the accompanying ladder diagram, the solid lines represent the His bundle, the dashes represent the RB, the dots represent the LB, and the solid horizontal bars denote the refractory period. P waves and the atrioventricular node are not identified. (Courtesy Dr. C. Fisch.)

FIGURE 12-29 Acceleration-dependent QRS aberration with the paradox of persistence at a longer cycle and normalization at a shorter cycle than that initiating the aberration. The duration of the basic cycle (C) is 760 milliseconds. LBBB appears at a cycle length of 700 milliseconds (dot) and is perpetuated at cycle lengths (arrow-head) of 800 and 840 milliseconds; conduction normalizes after a cycle length of 600 milliseconds. Perpetuation of LBBB at cycle lengths of 800 and 840 milliseconds is probably caused by transseptal concealment, similar to that described in Figure 12-27. Unexpected normalization of the QRS (S) after the atrial premature contraction probably is caused by equalization of conduction in the two bundles. (From Fisch C, Zipes DP, McHenry PL: Rate dependent aberrancy. *Circulation* 48:714, 1973.)

of transient aberration (see Chapter 33), can occur at relatively high or low heart rates. In *acceleration (tachycardia)-dependent block*, conduction delay occurs when the heart rate exceeds a critical value. At the cellular level, this aberration is the result of encroachment of an impulse on the relative refractory period of the preceding beat, which results in slower conduction. This form of rate-related block is relatively common and can have the ECG pattern of RBBB or LBBB (Figs. 12-28 and 12-29).

In deceleration (bradycardia)-dependent block, conduction delay occurs when the heart rate falls below a critical level. This may reflect abnormal phase 4 depolarization of cells causing activation to occur at lower resting potentials. Deceleration-dependent block is less common than acceleration-dependent block and usually is seen only in patients with significant conduction system disease (Fig. 12-30).

Other mechanisms of ventricular aberration include concealed conduction in the bundle branches (see Figs. 12-28 and 12-29), preexcitation syndromes (Chapter 37), depressed myocardial conduction from drugs or hyperkalemia (see Fig. 12-47, top), and the effect of changing cycle length on refractoriness (the Ashman phenomenon) (see Fig. 12-28 and Chapter 33). Table 12-8 summarizes the major causes of a wide QRS occurring at physiologic heart rates. The more specific topic of wide complex tachycardias is discussed in Chapters 34 and 37.

Other Forms of Conduction Abnormalities. *Notching or fragmentation* refers to the presence of multiple deflections within the QRS complex (e.g., rSr, Rsr', rSR'' or multiple r' patterns) or the presence of high-frequency notches within the R and S wave without overall prolongation of the QRS complex. These aberrancies may

reflect disruptions in the normally smooth patterns of activation by scarring, as in patients who have had multiple infarctions.⁵¹

Peri-infarction block is an older but still useful term that refers to conduction delay in the region of a myocardial infarction. It is manifested in ECG leads by pathologic Q waves when the terminal portion of the QRS complex is wide and directed opposite to the Q wave, such as a QR complex in leads III and aVF. A related abnormality is *peri-ischemic block*, manifested by a reversible widening of the QRS complex in leads with ST-segment elevation caused by acute injury.

The term *nonspecific intraventricular conduction defect* is often used to refer to patterns with a widened QRS complex (greater than 120 milliseconds) but without the specific patterns characteristic of RBBB or LBBB.

Myocardial Ischemia and Infarction

The ECG remains a key test for the diagnosis of acute and chronic coronary syndromes.⁵²⁻⁶⁰ The

findings vary considerably, depending on four major factors: (1) the duration of the ischemic process (acute versus evolving/chronic); (2) its extent (size and transmural location); (3) its topography (anterior versus inferior-posterior-lateral or right ventricular); and (4) the presence of other underlying abnormalities (e.g., LBBB, Wolff-Parkinson-White [WPW] syndrome, or pacemaker patterns) that can mask or alter the classic patterns.

A critical clinical distinction is between *ST-segment elevation myocardial infarction* (or ischemia) (STEMI) and *non-STEMI infarction* (or ischemia) because of the therapeutic implications. Emergency coronary reperfusion therapy has proved to be consistently efficacious only in the former syndromes.

FIGURE 12-30 Deceleration-dependent aberration. The basic rhythm is sinus with a Wenckebach (type I) atrioventricular block. With 1:1 atrioventricular conduction, the QRS complexes are normal in duration; with a 2:1 atrioventricular block or after the longer pause of a Wenckebach sequence, LBBB appears. (Courtesy Dr. C. Fisch.)

Repolarization (ST-T Wave) Abnormalities

The earliest and most consistent ECG finding during acute severe ischemia is deviation of the ST segment as a result of a current of injuries (see Chapter 51). Under normal conditions, the ST segment usually is nearly isoelectric, because almost all healthy myocardial cells attain approximately the same potential during the initial to middle phases of repolarization, corresponding to the plateau phase of the ventricular action potential.

Ischemia, however, produces complex time-dependent effects on the electrical properties of myocardial cells. Severe acute ischemia can reduce the resting membrane potential, shorten the duration of the action potential, and decrease the rate of rise and amplitude of phase 0 in the ischemic area (Fig. 12-31). The key concept is that these perturbations cause a *voltage gradient* between normal and ischemic zones that leads to current flow between these regions. The resulting *injury currents* are represented on the surface ECG as deviations of the ST segment.

The precise electrophysiologic mechanisms underlying injury currents and their directionality with ischemia and related conditions remains an area of active research and some controversy even after decades of study. Both “diastolic” and “systolic” injury currents have been proposed, based primarily on animal studies, to explain ischemic ST-segment elevations^{56,58} (Fig. 12-32). According to the diastolic current of injury hypothesis, ischemic ST-segment elevation is attributable to negative (downward) displacement of the electrical diastolic baseline (the TQ segment of the ECG). Ischemic cells remain relatively depolarized, probably related importantly to potassium ion leakage, during phase 4 of the ventricular action potential (i.e., lower membrane resting potential; see Fig. 12-31) and depolarized muscle carries a negative extracellular charge relative to repolarized muscle. Therefore, during electrical diastole, current (the diastolic current of injury) will flow between the partly or completely depolarized ischemic myocardium and the neighboring, normally repolarized, uninjured myocardium. The injury current vector will be directed away from the more negative ischemic zone toward the more positive normal myocardium. As a result, leads overlying the ischemic zone will record a negative deflection during electrical diastole and produce depression of the TQ segment.

TQ-segment depression, in turn, appears as ST-segment elevation, because the ECG recorders in clinical practice use alternating current-coupled amplifiers that automatically “compensate” or adjust for any negative shift in the TQ segment. As a result of this electronic effect, the ST segment will be proportionately elevated. Therefore, according to the diastolic current of injury theory, ST-segment elevation

FIGURE 12-31 Acute ischemia may alter ventricular action potentials in a number of ways that result in lower resting membrane potential, decreased amplitude and velocity of phase 0, and an abbreviated action potential duration (a pathologic form of early repolarization). These electrophysiologic effects, singly or in combination, create a voltage gradient between ischemic and normal cells during different phases of the cardiac electrical cycle. The resulting currents of injury are reflected on the surface ECG by deviation of the ST segment (see Fig. 12-32).

FIGURE 12-32 A simplified scheme of the pathophysiology of ischemic ST elevation. Two basic mechanisms have been advanced to explain the ST elevation seen with acute myocardial injury. **A**, Diastolic current of injury. In this case (first QRS-T complex), the ST vector will be directed away from the relatively negative, partly depolarized ischemic region during electrical diastole (TQ interval), and the result will be primary TQ depression. Conventional alternating current ECGs “compensate” for the baseline shift, and apparent ST-segment elevation (second QRS-T complex) results. **B**, Systolic current of injury. In this scenario, the ischemic zone will be relatively positive during electrical systole because the cells are repolarized early, and the amplitude and upstroke velocity of their action potentials may be decreased. This so-called systolic injury current vector will be oriented toward the electropositive zone, and the result will be primary ST-segment elevation. In clinical recordings, the contributions of diastolic and systolic injury currents to the observed ST-segment elevation cannot be determined (see text).

represents an apparent shift. The true shift, observable only with direct current-coupled ECG amplifiers, is the negative displacement of the TQ baseline.

Evidence also suggests that ischemic ST-segment elevations (and hyperacute T waves) may also be related to systolic injury currents. Three factors may make acutely ischemic myocardial cells relatively positive in comparison with normal cells with respect to their extracellular charge during electrical systole (QT interval): (1) pathologic early repolarization (shortened action potential duration); (2) decreased action potential upstroke velocity; and (3) decreased action potential amplitude (see Fig. 12-34). The presence of one or more of these effects will establish a voltage gradient between normal and ischemic zones during the QT interval such that the current of injury vector will be directed toward the ischemic region. This systolic current of injury mechanism, also probably related in part to potassium leakage, will result in primary ST-segment elevation, sometimes with tall, positive (hyperacute) T waves.

When acute ischemia is transmural, the overall ST vector (whether caused by diastolic or systolic injury currents, or both) usually is shifted in the direction of the outer (epicardial) layers, and ST-segment elevation and sometimes tall, positive (hyperacute) T waves are produced over the ischemic zone (Fig. 12-33). Reciprocal ST-segment depression can appear in leads reflecting the contralateral surface of the heart. Occasionally, the reciprocal changes can be more apparent than the primary ST-segment elevations.

When ischemia is confined primarily to the subendocardium, the overall ST vector typically shifts toward the inner ventricular layer and the ventricular cavity such that the overlying (e.g., anterior precordial) leads show ST-segment depression, with ST-segment elevation in lead aVR (see Fig. 12-33). This subendocardial ischemia pattern is the

typical finding during spontaneous episodes of angina pectoris or during symptomatic or asymptomatic (silent) ischemia induced by exercise or pharmacologic stress tests (see Chapter 13). However, inspection of the surface ECG, with either ST elevation or ST depression ischemia, cannot differentiate between the contributions of systolic and diastolic currents of injury.

Multiple factors can affect the amplitude of acute ischemic ST-segment deviations. Profound ST-segment elevation or depression in multiple leads usually indicates very severe or widespread ischemia. Conversely, prompt resolution of ST-segment elevation after

thrombolytic therapy or percutaneous coronary interventions⁵⁹ is a specific marker of successful reperfusion. These relationships are not universal, however, because severe ischemia or even infarction can occur with slight or absent ST-T changes. Furthermore, a relative increase in T wave amplitude (hyperacute T waves) can accompany or precede the ST-segment elevations with ischemia with or without infarction (Fig. 12-34).

QRS Changes

With actual infarction, depolarization (QRS) changes often accompany repolarization (ST-T) abnormalities (Fig. 12-35). Necrosis of sufficient myocardial tissue can lead to decreased R wave amplitude or Q waves in the anterior, lateral, or inferior leads as a result of loss of electromotive forces in the infarcted area. Local conduction delays caused by acute ischemia also can contribute to Q wave pathogenesis in selected cases.

Abnormal Q waves were once considered markers of transmural myocardial infarction, whereas subendocardial (nontransmural) infarcts were thought not to produce Q waves. However, careful experimental and clinical electrocardiographic-pathologic correlative studies have indicated that transmural infarcts can occur without Q waves and that subendocardial infarcts can be associated with Q waves.^{53,56,61} Accordingly, infarcts are better classified electrocardiographically as Q wave or non-Q wave, rather than as transmural or nontransmural, based on the ECG.

The findings may be somewhat different with posterior or lateral infarction (Fig. 12-36). Loss of depolarization forces in these regions can reciprocally increase R wave amplitude in lead V₁ and sometimes V₂, rarely without causing diagnostic Q waves in any of the conventional leads. The differential diagnosis for major causes of prominent right precordial R waves is presented in Table 12-9.

Evolution of Electrocardiographic Changes

Ischemic ST-segment elevation and hyperacute T wave changes may occur as the earliest ECG manifestations of acute infarction (STEMI) and typically are followed within a period ranging from hours to days by evolving T wave inversion and sometimes Q waves in the same lead distribution (see Fig. 12-35 and Chapter 51). T wave inversion from evolving or chronic ischemia correlates with increased ventricular action potential duration, and these ischemic changes are often associated with QT prolongation. The T wave inversions can resolve after days or weeks or may persist indefinitely.

FIGURE 12-33 Directionality of current of injury patterns (ST vectors) with acute ischemia. **A**, With predominant subendocardial ischemia, the resultant ST vector is directed toward the inner layer of the affected ventricle and the ventricular cavity. Overlying leads therefore record ST depression, as may be seen during abnormal exercise stress tests or with spontaneous angina pectoris. **B**, With ischemia involving the outer ventricular layer (transmural or epicardial injury), the ST vector is directed outward. Overlying leads record ST-segment elevation. Reciprocal ST-segment depression can appear in contralateral leads.

FIGURE 12-34 Hyperacute phase of extensive anterolateral myocardial infarction. Marked ST-segment elevation melding with prominent T waves is present across the precordium, as well as in leads I and aVL. ST-segment depression, consistent with a reciprocal change, is seen in leads III and aVF. Q waves are present in leads V₃ through V₆. Marked ST-segment elevations with tall T waves caused by severe ischemia are sometimes referred to as a monophasic current of injury pattern. A paradoxical increase in R wave amplitude (V₂ and V₃) may accompany this pattern. This tracing also shows left axis deviation with small or absent inferior R waves, which raises the possibility of a previous inferior infarct.

FIGURE 12-35 Sequence of depolarization and repolarization changes with acute anterior-lateral (A) and acute inferior wall (B) Q wave infarctions. With anterior-lateral infarcts, ST-segment elevation in leads I, aVL, and the precordial leads can be accompanied by reciprocal ST-segment depression in leads II, III, and aVF. Conversely, acute inferior (or posterior) infarcts can be associated with reciprocal ST-segment depression in leads V₁ to V₃. (A, B, From Goldberger AL, Goldberger ZD, Shvilkin A: *Goldberger's Clinical Electrocardiography: A Simplified Approach*. 8th ed. Philadelphia, Saunders, 2012.)

FIGURE 12-36 Evolving infero-posterolateral infarction. Note the prominent Q waves in II, III, and aVF, along with ST-segment elevation and T wave inversion in these leads, as well as V₃ through V₆. ST depression in I, aVL, V₁, and V₂ is consistent with a reciprocal change. Relatively tall R waves also are present in V₁ and V₂.

The extent of the infarct may be an important determinant of T wave evolution. In one series of ECGs,⁶² T waves that were persistently negative for more than 1 year in leads with Q waves were associated with a transmural infarction with fibrosis of the entire wall; by contrast, T waves that were positive in leads with Q waves correlated with non-transmural infarction, with viable myocardium within the wall.

In the days to weeks or longer after infarction, the QRS changes can persist or begin to resolve.^{56,63} Complete normalization of the ECG after Q wave infarction is uncommon but can occur, particularly with smaller infarcts and with subsequent improvement of the left ventricular ejection fraction and regional wall motion. This development usually is associated with spontaneous recanalization or good collateral circulation and is a positive prognostic sign. By contrast, persistent Q waves and ST-segment elevation seen several weeks or more

after infarction correlate strongly with a severe underlying wall motion disorder (akinetic or dyskinetic zone), although not necessarily a frank ventricular aneurysm. The presence of an rSR' or similar type of complex in the mid-left chest leads or lead I is another reported marker of a left ventricular aneurysm.

Other Ischemic ST-T Patterns

Reversible transmural ischemia caused, for example, by coronary vasospasm may result in very transient ST-segment elevation^{53,54} (Fig. 12-37). This pattern is the classic ECG marker of *Prinzmetal variant angina* (see Chapters 53 and 54). Depending on the severity and duration of such noninfarction ischemia, the ST-segment elevation can either resolve completely within minutes or be followed by T wave inversion, which can persist for hours or even days.

Displacement of heart toward right side of chest (dextroversion), congenital or acquired
Myocardial Injury
Lateral or “true posterior” myocardial infarction
Duchenne muscular dystrophy (see Chapter 87)
Ventricular Enlargement
RVH (usually with right axis deviation)
Hypertrophic cardiomyopathy
Altered Ventricular Depolarization
Right ventricular conduction abnormalities
WPW patterns (caused by posterior or lateral wall preexcitation)

Modified from Goldberger AL: *Clinical Electrocardiography: A Simplified Approach*. 7th ed. St. Louis, CV Mosby, 2006.

Some patients with ischemic chest pain exhibit deep coronary T wave inversion in multiple precordial leads (e.g., V₁ through V₄), with or without cardiac enzyme level elevations. This finding typically is the result of severe ischemia associated with a high-grade stenosis in the proximal left anterior descending (LAD) coronary artery system (referred to as the LAD–T wave pattern). The T wave inversion can actually be preceded by a transient ST-segment elevation that resolves by the time the patient arrives at the hospital. These T wave inversions, in the setting of unstable angina, can correlate with segmental hypokinesis of the anterior wall and suggest a myocardial stunning syndrome. The natural history of this syndrome is unfavorable, with a high incidence of recurrent angina and myocardial infarction.

On the other hand, patients whose baseline ECG already shows abnormal T wave inversion can experience paradoxical T wave normalization (pseudonormalization) during episodes of acute transmural ischemia (Fig. 12-38). The four major classes of acute electrocardiographic coronary artery syndromes in which myocardial ischemia leads to different ECG findings are summarized in Figure 12-39.

FIGURE 12-37 A, ECG tracing from a patient with Prinzmetal angina with ST-segment elevation and ST-T wave (repolarization) alternans. B, This tracing shows ST segment and T wave alternans associated with nonsustained ventricular tachycardia. (A, B, Courtesy Dr. C. Fisch.)

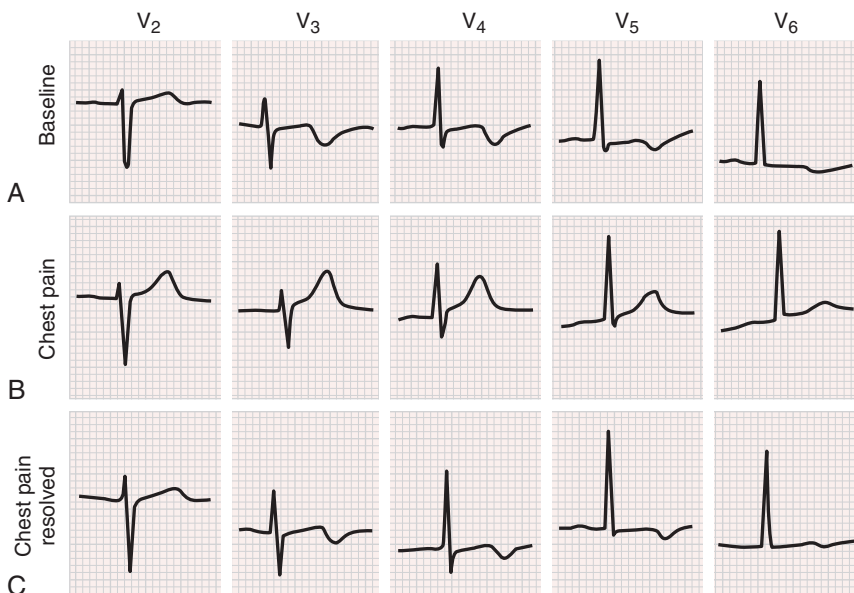

FIGURE 12-38 Pseudo- (paradoxical) T wave normalization. A, Baseline ECG of a patient with coronary artery disease shows ischemic T wave inversion. B, T wave “normalization” during an episode of ischemic chest pain. C, After resolution of the chest pain, the T waves have reverted to their baseline appearance (A, B, From Goldberger AL, Goldberger ZD, Shvilkin A: *Goldberger’s Clinical Electrocardiography: A Simplified Approach*. 8th ed. Philadelphia, Saunders, 2012.)

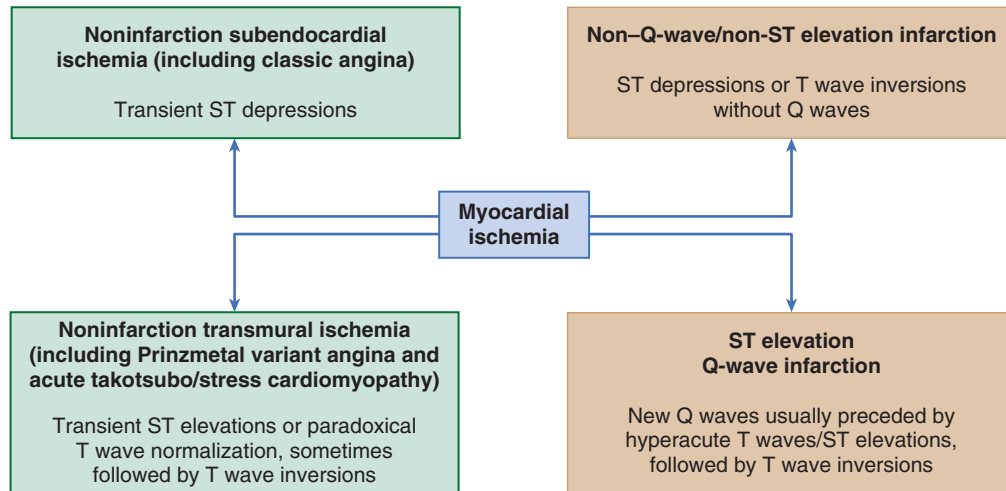

FIGURE 12-39 Variability of ECG patterns with acute myocardial ischemia. The ECG also may be normal or nonspecifically abnormal. Furthermore, these categorizations are not mutually exclusive. For example, a non-Q-wave infarct can evolve into a Q wave infarct, ST-segment elevation can be followed by a non-Q-wave infarct or ST-segment depression, and T wave inversion can be followed by a Q wave infarct. (From Goldberger AL, Goldberger ZD, Shvilkin A: *Goldberger's Clinical Electrocardiography: A Simplified Approach*. 8th ed. Philadelphia, Saunders, 2012.)

FIGURE 12-40 Acute right ventricular infarction with acute inferior wall infarction. Note the ST-segment elevation in the right precordial leads, as well as in leads II, III, and aVF, with reciprocal changes in leads I and aVL. ST-segment elevation in lead III greater than in lead II and right precordial ST-segment elevation are consistent with proximal to middle occlusion of the right coronary artery. The combination of ST-segment elevation in conventional lead V₁ (V_{2R} here) and ST-segment depression in lead V₂ (lead V_{1R} here) also has been reported with acute right ventricular ischemia or infarction.

Ischemic U Wave Changes

Alterations in U wave amplitude or polarity have been reported with acute ischemia or infarction.⁶⁴ For example, exercise-induced transient inversion of precordial U waves has been correlated with severe stenosis of the LAD coronary artery. Rarely, U wave inversion can be the earliest ECG sign of an acute coronary syndrome.

Electrocardiographic Localization of Myocardial Ischemia and Infarction

The ECG leads are more helpful in localizing regions associated with ST-segment elevation than with ST-segment depression. As examples, ST-segment elevation and/or hyperacute T waves are seen in the following: (1) two or more contiguous precordial leads (V₁ through V₆) and/or in leads I and aVL with acute transmural anterior or anterolateral wall ischemia; (2) leads V₁ to V₃ with anteroseptal or apical⁶⁵ ischemia; (3) leads V₄ to V₆ with apical or lateral ischemia; (4) leads II, III, and aVF with inferior wall ischemia; and (5) right-sided precordial leads with right ventricular ischemia.

Posterior or posterolateral wall infarction, which induces ST-segment elevation in leads placed over the back of the heart, such as

leads V₇ to V₉ (see Table 12-4), can be produced by lesions in the right coronary artery or the left circumflex artery. Such blockages can produce both inferior and posterolateral injuries, which may be indirectly recognized by reciprocal ST-segment depression in leads V₁ to V₃. Similar ST changes also can be the primary ECG manifestation of anterior subendocardial ischemia. Posterolateral or inferolateral wall infarction with reciprocal changes can sometimes be differentiated from primary anterior wall ischemia by the presence of ST-segment elevations in posterior leads, although these are not routinely recorded.

The ECG also can provide more specific information about the location of the occlusion within the coronary system (the culprit lesion).^{6,53,57,59,66-68} In patients with an inferior wall myocardial infarction, the presence of ST-segment elevation in lead III exceeding that in lead II, particularly when combined with elevation in lead V₁, is a useful predictor of occlusion in the proximal to midportion of the right coronary artery (Fig. 12-40). By contrast, the presence of ST-segment elevation in lead II equal to or exceeding that in lead III, especially in concert with ST-segment depression in leads V₁ to V₃ or ST-segment elevation in leads I and aVL, suggests occlusion of the

FIGURE 12-41 RBBB with acute anterior infarction. Loss of anterior depolarization forces results in QR-type complexes in the right precordial to midprecordial leads, with ST-segment elevations and evolving T wave inversions (V₁ through V₆).

left circumflex coronary artery or a distal occlusion of a dominant right coronary artery.

Right-sided ST-segment elevation is indicative of acute right ventricular injury and usually indicates occlusion of the proximal right coronary artery. Of note is the finding that acute right ventricular infarction can project an injury current pattern in leads V₁ through V₃ or even V₄, thus simulating anterior infarction. In other cases, simultaneous ST-segment elevation in V₁ (V₂R) and ST-segment depression in V₂ (V₁R) can occur (Fig. 12-41).

Lead aVR may provide important clues to artery occlusion in myocardial infarction. Left main (or severe multivessel) disease should be considered when leads aVR and V₁ show ST-segment elevation, especially in concert with diffuse prominent ST-segment depression in other leads.

These and multiple other criteria proposed for localization of the site of acute coronary occlusion based on the initial ECG still require additional validation in larger populations. Current and future criteria will always be subject to limitations and exceptions based on variations in coronary anatomy, the dynamic nature of acute ECG changes, the presence of multivessel involvement, collateral flow, and the presence of ventricular conduction delays.

For example, in some cases, ischemia can affect more than one region of the myocardium (e.g., inferolateral; see Fig. 12-35). Not uncommonly, the ECG will show the characteristic features of involvement in each region. Sometimes, however, partial normalization can result from cancellation of opposing vectorial forces. Inferior lead ST-segment elevation accompanying acute anterior wall infarction suggests either occlusion of a left anterior descending artery that extends onto the inferior wall of the left ventricle (the wrap-around vessel) or multivessel disease with jeopardized collaterals.

Electrocardiographic Diagnosis of Bundle Branch Blocks and Myocardial Infarction. The diagnosis of

myocardial infarction often is more difficult in cases in which the baseline ECG shows a bundle branch block pattern, or when bundle branch block develops as a complication of the infarction. The diagnosis of Q wave infarction usually is not impeded by the presence of RBBB, which affects primarily the terminal phase of ventricular depolarization. The net effect is that the criteria for the diagnosis of a Q wave infarct in a patient with RBBB are the same as in patients with normal conduction (see Fig. 12-41).

The diagnosis of infarction in the presence of LBBB is considerably more complicated and confusing, because LBBB alters the early and the late phases of ventricular depolarization and produces secondary ST-T changes. These changes may mask and/or mimic myocardial infarction findings. As a result, considerable attention has been directed to the problem of diagnosing acute and chronic myocardial infarction in patients with LBBB⁶⁹ (Fig. 12-42).

Infarction of the left ventricular free (or lateral) wall ordinarily results in abnormal Q waves in the midprecordial to lateral precordial leads (and selected limb leads). However, the initial septal depolarization forces with LBBB are directed from right to left. These leftward forces produce an initial R wave in the midprecordial to lateral precordial leads, usually masking the loss of electrical potential (Q waves) caused by the infarction. Therefore acute or chronic left ventricular free wall infarction by itself will not usually produce diagnostic Q waves in the presence of LBBB. Acute or chronic infarction involving both the free wall and septum (or the septum itself) may produce abnormal Q waves (usually as part of QR-type complexes) in leads V₄ to V₆. These initial Q waves probably reflect posterior and superior forces from the spared basal portion of the septum (Fig. 12-43). Thus a wide Q wave (40 milliseconds) in one or more of these leads is a reliable sign of underlying infarction. The sequence of repolarization also is altered in LBBB, with the ST segment and T wave vectors being directed opposite that of the QRS complex. These changes can mask or simulate the ST-segment changes of actual ischemia.

The following points summarize the ECG signs of myocardial infarction in LBBB:

1. ST-segment elevation with tall, positive T waves frequently is seen in the right precordial leads with uncomplicated LBBB. Secondary T wave inversions are characteristically seen in the lateral precordial leads. However, the appearance of ST-segment elevations in the lateral leads or ST-segment depressions or deep T wave inversions in leads V₁ to V₃ strongly suggests underlying ischemia. More marked ST-segment elevations (>0.5 mV) in leads with QS or rS waves also may be caused by acute ischemia, but false-positive

FIGURE 12-42 Complete LBBB with acute inferior myocardial infarction. Note the prominent ST-segment elevation in leads II, III, and aVF, with reciprocal ST-segment depression in leads I and aVL superimposed on secondary ST-T changes. The underlying rhythm is atrial fibrillation.

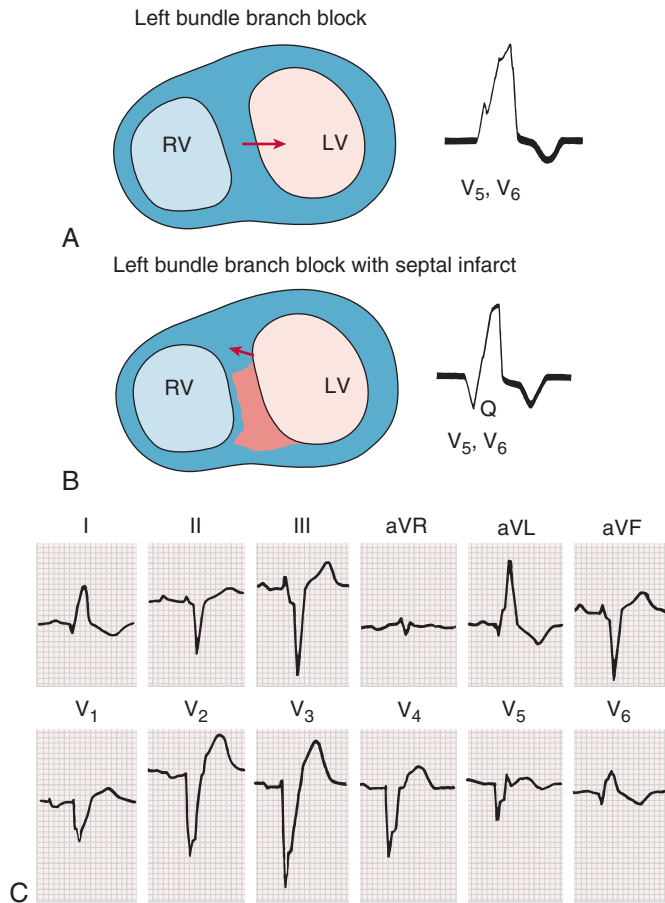

FIGURE 12-43 **A**, With uncomplicated LBBB, early septal forces are directed to the left (arrow on the diagram). Therefore no Q waves will be seen in V_5 and V_6 on the ECG tracing. **B**, With LBBB complicated by anteroseptal infarction, early septal forces can be directed posteriorly and rightward (arrow). Therefore prominent Q waves may appear in leads V_5 and V_6 as a paradoxical marker of septal infarction. **C**, ECG from patient with anterior wall infarction (involving septum) with LBBB. Note the presence of QR complexes in leads I, aVL, V_5 , and V_6 . LV = left ventricle; RV = right ventricle. (**A B**, Modified from Dunn MI, Lipman BS: *Lipman-Massie Clinical Electrocardiography*. 8th ed. Chicago, Year Book, 1989.)

findings occur, especially with large-amplitude negative QRS complexes. Use of the ratio of the amplitude of ST-segment elevation to S wave magnitude, determined in any relevant lead, has been proposed, with a value of less than 0.25 reported as having greater accuracy than that of the original criterion.⁷⁰ Further studies are needed to confirm this finding.

2. The presence of QR complexes in leads I, V_5 , or V_6 or in II, III, and aVF with LBBB strongly suggests underlying infarction.
3. Chronic infarction also is suggested by notching of the ascending part of a wide S wave in the midprecordial leads or the ascending limb of a wide R wave in lead I, aVL, V_5 , or V_6 .

Similar principles can apply to the diagnosis of acute and chronic infarction in the presence of right ventricular pacing. Comparison between an ECG exhibiting the LBBB before the infarction and the present ECG often is helpful to show these changes.

The diagnosis of concomitant LAFB and inferior wall infarction also can pose challenges. This combination can result in loss of the small r waves in the inferior leads, so that leads II, III, and aVF show QS, not rS, complexes. LAFB, however, occasionally will hide the diagnosis of inferior wall infarction. The inferior orientation of the initial QRS forces caused by the fascicular block can mask inferior Q waves, with resultant rS complexes in leads II, III, and aVF. In other cases, the combination of LAFB and inferior wall infarction will produce qrS complexes in the inferior limb leads, with the initial q wave the result of the infarct and the minuscule r wave the result of the fascicular block.

Atrial Infarction. A number of ECG clues to the diagnosis of atrial infarction have been suggested. These include localized deviations of

the PR segment, such as PR elevation in lead V_5 or V_6 or the inferior leads,^{69,71} changes in P wave morphology, and atrial arrhythmias. The sensitivity and specificity of these signs are limited, however. Diffuse PR segment changes (PR elevation in aVR with depression in the inferolateral leads) with acute ventricular infarction usually indicates concomitant pericarditis (see later).

Electrocardiographic Differential Diagnosis of Ischemia and Infarction

The ECG has important limitations in sensitivity and specificity in the diagnosis of coronary syndromes.^{52,53,56} An initially normal ECG does not exclude ischemia or even acute infarction.^{72,73} If the initial ECG is not diagnostic, but the patient remains symptomatic, with a clinical picture strongly suggestive of acute ischemia, the ECG should be repeated at 5- to 10-minute intervals.⁵⁵ However, a normal ECG throughout the course of a suspected acute infarction is distinctly uncommon. As a result, prolonged chest pain without suggestive or diagnostic electrocardiographic changes on repeat ECGs should always prompt a careful search for noncoronary causes of chest pain (see Chapter 50). Pathologic Q waves can be absent, even in patients with depressed left ventricular function caused by severe coronary disease and a previous infarct. As noted, the diagnosis of acute or chronic infarction can be completely masked by ventricular conduction disturbances, especially those resulting from LBBB, as well as ventricular pacing and WPW preexcitation. On the other hand, diagnostic confusion can arise because Q waves, ST-segment elevation, ST-segment depression, tall positive T waves, and deep T wave inversion can be seen in a wide variety of noncoronary settings.

Noninfarction Q Waves. Loss of electromotive force associated with myocardial necrosis contributes to R wave loss and Q wave formation in myocardial infarction. This mechanism of Q wave pathogenesis, however, is not specific for coronary artery disease with infarction. Any process, acute or chronic, that causes sufficient loss of regional electromotive potential can result in Q waves. For example, replacement of myocardial tissue by electrically inert material such as amyloid or tumor can cause noninfarction Q waves (see Chapters 65 and 85). A variety of dilated cardiomyopathies associated with extensive myocardial fibrosis can be characterized by pseudoinfarction patterns. Ventricular hypertrophy also can contribute to Q wave pathogenesis in this setting.

Q waves simulating the electrocardiographic pattern of coronary artery disease can be related to one (or a combination) of the following four factors⁵⁶ (Table 12-10): (1) physiologic or positional variants; (2) altered ventricular conduction; (3) ventricular enlargement; and (4) myocardial damage or replacement. Depending on the electrical axis, prominent Q waves (as part of QS- or QR-type complexes) also can appear in the limb leads (aVL with a vertical axis and III and aVF with a horizontal axis). A QS complex can appear in lead V_1 as a normal variant, but rarely in leads V_1 and V_2 . Prominent Q waves can be associated with a variety of other positional factors that alter the orientation of the heart vis-à-vis a specific lead axis. Poor R wave progression, sometimes with actual QS waves, can be caused solely by improper placement of chest electrodes above their usual position. With dextrocardia, in the absence of underlying structural abnormalities, normal R wave progression can be restored by recording leads V_2 to V_6 on the right side of the chest (with lead V_1 placed in the V_2 position). A rightward mediastinal shift in the left pneumothorax can contribute to the apparent loss of left precordial R waves. Other positional factors associated with slow R wave progression include pectus excavatum and congenitally corrected transposition of the great vessels.

An intrinsic change in the sequence of ventricular depolarization can lead to pathologic, noninfarct Q waves. The two most important conduction disturbances associated with pseudoinfarction Q waves are LBBB and the WPW preexcitation patterns. With LBBB, QS complexes can appear in the right precordial to midprecordial leads and, occasionally, in one or more of leads II, III, and aVF. Depending on the location of the bypass tract, WPW preexcitation can mimic anteroseptal, lateral, or inferior-posterior infarction. LAFB often is cited as a cause of anteroseptal infarct patterns; however, LAFB usually has

only minor effects on the QRS complex in horizontal plane leads. Probably the most common findings are relatively prominent S waves in leads V₅ and V₆. Slow R wave progression is not a consistent feature of LAFB, although minuscule q waves in leads V₁ to V₃ have been reported in this setting. These small q waves can become more apparent if the leads are recorded one interspace above their usual position and disappear in leads that are one interspace below their usual position. As a general clinical rule, however, prominent Q waves (as part of QS or QR complexes) in the right precordial to midprecordial leads should not be attributed to LAFB alone.

Q waves caused by myocardial injury, whether ischemic or nonischemic in origin, can appear transiently and do not necessarily signify irreversible heart muscle damage; severe ischemia can cause regional loss of electromotive potential without actual cell death (*electrical stunning* phenomenon). Transient conduction disturbances also can cause alterations in ventricular activation and result in non-infarctional Q waves. In some cases, transient Q waves may represent

unmasking of a previous Q wave infarct. New but transient Q waves have been described in patients with severe hypotension from a variety of causes, as well as with tachyarrhythmias, myocarditis, Prinzmetal angina, protracted hypoglycemia, phosphorus poisoning, and hyperkalemia.

Slow (“poor”) R wave progression, a nonspecific finding, commonly is observed with LVH and with acute or chronic right ventricular overload. Q waves in such settings can reflect a variety of mechanisms, including a change in the balance of early ventricular depolarization forces and altered cardiac geometry and position. A marked loss of R wave voltage, sometimes with frank Q waves from lead V₁ to the lateral chest leads, can be seen with chronic obstructive pulmonary disease (see Fig. 12-20). The presence of low limb voltage and signs of right atrial abnormality (P pulmonale) can serve as additional diagnostic clues. This loss of R wave progression may, in part, reflect right ventricular dilation. Furthermore, downward displacement of the heart in an emphysematous chest can play a major role in the genesis of poor R wave progression in this syndrome. Partial or complete normalization of R wave progression can be achieved in these cases simply by recording the chest leads an interspace lower than usual (see Fig. 12-20).

Other Pseudoinfarction Patterns in Ventricular Overload. A variety of pseudoinfarction patterns can occur with acute cor pulmonale caused by pulmonary embolism (see Chapter 73). Acute right ventricular overload in this setting can cause slow R wave progression and sometimes right precordial to midprecordial T wave inversion (formerly referred to as right ventricular strain), mimicking anterior ischemia or infarction. The classic S₁Q₃T₃ pattern can occur but is neither sensitive nor specific. A prominent Q wave (usually as part of a QR complex) also can occur in lead aVF along with this pattern (see Fig. 12-21). However, acute right overload by itself does not cause a pathologic Q wave in lead II. Right-sided heart overload, acute or chronic, also may be associated with a QR complex in lead V₁, simulating anteroseptal infarction.

Pseudoinfarction patterns are an important finding in patients with hypertrophic cardiomyopathy, and the ECG changes can simulate those in anterior, inferior, posterior, or lateral infarction. The pathogenesis of depolarization abnormalities in this cardiomyopathy is not certain. Prominent inferolateral Q waves (leads II, III, aVF, and V₄ to V₆) and tall, right precordial R waves probably are related to increased depolarization forces generated by the markedly hypertrophied septum (Fig. 12-44). Abnormal septal depolarization also can contribute to bizarre QRS complexes.

ST-T Changes Simulating Ischemia. The differential diagnosis of STEMI (or ischemia)⁵²⁻⁵⁸ caused by obstructive coronary disease encompasses a wide variety of clinical entities, including acute

TABLE 12-10 Differential Diagnosis of Noninfarction Q Waves (with Selected Examples)

Physiologic or Positional Factors
Normal variant “septal” Q waves Normal variant Q waves in V ₁ -V ₂ , III, and aVF Left pneumothorax or dextrocardia—loss of lateral R wave progression
Myocardial Injury or Infiltration
Acute processes—myocardial ischemia without infarction, myocarditis, hyperkalemia (rare cause of transient Q waves) Chronic myocardial processes—idiopathic cardiomyopathies, myocarditis, amyloid, tumor, sarcoid
Ventricular Hypertrophy or Enlargement
Left ventricular (slow R wave progression)* Right ventricular (reversed R wave progression† or poor R wave progression, particularly with chronic obstructive lung disease) Hypertrophic cardiomyopathy (can simulate anterior, inferior, posterior, or lateral infarcts)
Conduction Abnormalities
LBbB (slow R wave progression*) WPW patterns

*Small or absent R waves in the right precordial to midprecordial leads.
†Progressive decrease in R wave amplitude from V₁ to the midlateral precordial leads.
Modified from Goldberger AL, Goldberger ZD, Shvilkin A: *Goldberger’s Clinical Electrocardiography: A Simplified Approach*. 8th ed. Philadelphia, Saunders, 2012.

FIGURE 12-44 Hypertrophic cardiomyopathy simulating inferolateral infarction. This ECG was obtained in an 11-year-old girl who had a family history of hypertrophic cardiomyopathy. Note the W-shaped QS waves and the qrS complexes in the inferior and lateral precordial leads. (From Goldberger AL, Goldberger ZD, Shvilkin A: *Goldberger’s Clinical Electrocardiography: A Simplified Approach*. 8th ed. Philadelphia, Saunders, 2012.)

pericarditis (see Chapter 71) (Fig. 12-45; see also Fig. 71-2), acute myocarditis (see Chapter 67), normal variants including classic early repolarization patterns (see Fig. 12-13), *takotsubo* (stress) cardiomyopathy,^{74,75} Brugada patterns (see Chapters 33 and 37), and a number of other conditions listed in Table 12-11. Acute pericarditis, in contrast with acute myocardial infarction, typically induces diffuse ST-segment elevation, usually in most of the chest leads and also in leads I, aVL, II, and aVF. Reciprocal ST-segment depression is seen in lead aVR. An important clue to acute pericarditis, in addition to the diffuse nature of the ST-segment elevation, is the frequent presence of PR-segment elevation in aVR, with reciprocal PR-segment depression in other leads, caused by a concomitant atrial current of injury (see Fig. 12-45). Abnormal Q waves do not occur with acute pericarditis, and the ST-segment elevation may be followed by T wave inversion after a variable period. Acute myocarditis can, in some patients, produce the exact electrocardiographic pattern of acute myocardial

infarction, including ST-segment elevation and Q waves. These myocarditic pseudoinfarction findings can be associated with a rapidly progressive course and increased mortality.

Takotsubo cardiomyopathy, also called *transient left ventricular ballooning syndrome* or stress cardiomyopathy, is characterized by reversible wall motion abnormalities of the left ventricular apex and midventricle.^{74,75} Patients, usually postmenopausal women, may present with chest pain, ST-segment elevations, and elevated cardiac enzyme levels, exactly mimicking acute myocardial infarction caused by obstructive coronary disease. The syndrome typically is reported in the setting of emotional or physiologic stress. Fixed epicardial coronary disease is absent. The exact pathophysiology is not known but may relate to coronary vasospasm or neurogenically mediated myocardial damage, resulting in a transmural (ST-segment elevation) injury current pattern.

A variety of factors such as digitalis, ventricular hypertrophy, hypokalemia, and hyperventilation can cause ST-segment depression mimicking that in subendocardial ischemia. Similarly, tall positive T waves do not invariably represent hyperacute ischemic changes but can reflect normal variants, hyperkalemia, cerebrovascular injury, and left ventricular volume loads resulting from mitral or aortic regurgitation, among other causes. ST-segment elevation, J point elevations, and tall positive T waves also are common findings in leads V₁ and V₂ with LBBB or LVH patterns. In addition, tall T waves may be seen occasionally in the left chest leads with LVH, especially with volume (diastolic) overload syndromes (see Fig. 12-18).

T Wave Inversions. When caused by physiologic variants, T wave inversion is sometimes mistaken for ischemia. T waves in the right precordial leads can be slightly inverted, particularly in leads V₁ and V₂. Some adults show persistence of the juvenile T wave pattern (see Fig. 12-12), with more prominent T wave inversion in right precordial to midprecordial leads showing an rS or RS morphology. Such patterns, especially associated with LBBB-type premature ventricular beats or relevant family history, also raise strong consideration of *arrhythmogenic right ventricular cardiomyopathy* (formerly called dysplasia).⁷⁶ The other major normal variant that can be associated with notable T wave inversion is the so-called early repolarization pattern (see Fig. 12-13). As described earlier, some subjects, especially athletes, with this variant have prominent, biphasic T wave inversion in association with the ST-segment elevation. This pattern, which may simulate the initial stages of an evolving infarct, is most prevalent in young black men and athletes. These functional ST-T changes probably are the result of regional disparities in repolarization and usually can be normalized by exercise. An important consideration in the differential diagnosis for such changes, especially in athletes, is apical hypertrophic cardiomyopathy.

TABLE 12-11 Differential Diagnosis of ST-Segment Elevation

Myocardial ischemia or infarction
Noninfarction, transmural ischemia (e.g., Prinzmetal angina pattern, takotsubo syndrome)
Acute myocardial infarction (due to obstructive coronary occlusion or other causes)
Post-myocardial infarction (ventricular aneurysm pattern)
Acute pericarditis
Normal variants (including the classic early repolarization pattern)
LVH, LBBB (V ₁ -V ₂ or V ₃ only)
Other (rarer) causes
Acute pulmonary embolism (right to mid-chest leads)
Brugada pattern (RBBB-like pattern and ST-segment elevations in right precordial leads)*
Class IC antiarrhythmic drugs*
Hypercalcemia*
DC cardioversion (immediately after procedure)
Hyperkalemia*
Hypothermia (J or Osborn wave)
Intracranial hemorrhage
Myocardial injury (e.g., due to trauma)
Myocarditis (may resemble myocardial infarction or pericarditis)
Tumor invading the left ventricle

*Usually most apparent in leads V₁ to V₂.

Modified from Goldberger AL, Goldberger ZD, Shvilkin A: *Goldberger's Clinical Electrocardiography: A Simplified Approach*. 8th ed. Philadelphia, Saunders, 2012.

FIGURE 12-45 Acute pericarditis often is characterized by two apparent injury currents, one atrial and the other ventricular. The atrial injury current vector (ST_a) usually is directed upward and to the right (see diagram at left) and produces PR-segment elevation in aVR, with reciprocal PR depression in II, V₅, and V₆. The ventricular injury current (ST_v) is directed downward and to the left, associated with ST-segment elevation in leads II, V₅, and V₆. This characteristic PR-ST segment discordance is illustrated in the bottommost tracing. Note the diffuse distribution of ST-segment elevation in acute pericarditis (e.g., I, II, and V₂ through V₆, with reciprocal changes in aVR and perhaps minimally in V₁). LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle. (From Goldberger AL: *Myocardial Infarction: Electrocardiographic Differential Diagnosis*. 4th ed. St. Louis, Mosby-Year Book, 1991.)

FIGURE 12-46 Deep T wave inversion can have various causes. In the *middle* tracing, note the marked QT prolongation in conjunction with the cerebrovascular accident (CVA) T wave pattern, caused here by subarachnoid hemorrhage. Apical hypertrophic cardiomyopathy (HCM) and takotsubo syndrome are other causes of deep T wave inversion that can be mistaken for ischemia from acute/evolving or chronic obstructive coronary disease. (From Goldberger AL: *Deep T wave inversions*. ACC Curr J Rev 5:28, 1996.)

Primary and Secondary T Wave Inversions

A variety of pathologic factors can alter repolarization, causing prominent T wave inversion (**Fig. 12-46**). As noted earlier, T wave alterations are classified as *primary* or *secondary*. Primary T wave changes are caused by alterations in the duration or morphology of ventricular action potentials in the absence of changes in the activation sequence. Examples are the effects of ischemia, drugs, and metabolic changes.

Prominent primary T wave inversions (or in some cases, tall positive T waves) also are a well-described feature of the ECG in cerebrovascular accidents, particularly with subarachnoid hemorrhage. The so-called cerebrovascular accident T wave pattern characteristically is seen in multiple leads, with a widely splayed appearance usually associated with marked QT prolongation (see **Figs. 12-46** and **92-18**). Some studies have implicated structural damage (myocytolysis) in the hearts of patients with such T wave changes, probably induced by excessive sympathetic stimulation mediated via the hypothalamus. A role for concomitant vagal activation in the pathogenesis of such T wave changes, which usually are associated with bradycardia, also has been postulated. Similar T wave changes have been reported after truncal vagotomy, radical neck dissection, and bilateral carotid endarterectomy. In addition, the massive diffuse T wave inversion seen in some patients after Stokes-Adams syncope may be related to a similar neurogenic mechanism. Patients with subarachnoid hemorrhage also can show transient ST-segment elevation, as well as arrhythmias, including torsades de pointes. Ventricular dysfunction can even occur.

In contrast with these primary T wave abnormalities, secondary T wave changes are caused by altered ventricular activation, without changes in action potential characteristics. Examples include bundle branch block, WPW preexcitation, and ventricular ectopic or paced beats. In addition, altered ventricular activation (associated with QRS interval prolongation) can induce T wave changes, which can persist for hours to days after normal ventricular depolarization has resumed.

The term *cardiac memory T wave* changes has been used in this context to describe repolarization changes following depolarization changes caused by ventricular pacing, intermittent LBBB, intermittent WPW preexcitation, and other alterations of ventricular activation⁷⁷ (see **Chapters 34 and 37**). T wave inversions also may occur. Finally, the term *idiopathic global T wave inversion* has been applied in cases in which no identifiable cause for often marked diffuse repolarization abnormalities can be found. An unexplained female preponderance has been reported.

Drug Effects

Numerous drugs can affect the ECG and often are associated with nonspecific ST-T alterations.^{52,53} More marked changes, as well as atrioventricular and intraventricular conduction disturbances, can occur with selected agents. The proarrhythmic effects of antiarrhythmic medications are described in **Chapters 9 and 35**.

The term *digitalis effect*⁷⁸ refers to the relatively distinctive “scooped” appearance of the ST-T complex and shortening of the QT interval, which correlates with abbreviation of the ventricular action potential duration (**Fig. 12-47**). Digitalis-related ST-T changes can be accentuated by an increased heart rate during exercise, with consequent false-positive results on stress testing (see **Chapter 13**). Digitalis effect can occur with therapeutic or toxic doses of the drug. The term *digitalis toxicity* refers specifically to systemic effects (nausea and anorexia, among other effects) or conduction disturbances and arrhythmias caused by drug excess or increased sensitivity.

The ECG effects and toxicities of other cardioactive agents can be anticipated in part from ion channel effects (see **Chapter 33**). Inactivation of sodium channels by class I agents (e.g., quinidine, procainamide, disopyramide, flecainide) can cause QRS prolongation. Class IA (e.g., quinidine) and class III agents (e.g., amiodarone, dronedarone, dofetilide, ibutilide, sotalol) can induce an acquired long QT(U) syndrome (see **Chapter 35**). Psychotropic drugs (e.g., tricyclic antidepressants and phenothiazines), which have class IA-like properties, also can lead to QRS and QT(U) prolongation (see **Chapter 86**). Toxicity can produce asystole or torsades de pointes. Right axis shift of the terminal 40-millisecond frontal plane QRS axis may be a helpful additional marker of tricyclic antidepressant overdose. QT prolongation has been reported with methadone. Cocaine (see **Chapter 68**) can cause a variety of ECG changes including those of STEMI, as well as life-threatening arrhythmias.

Electrolyte and Metabolic Abnormalities

In addition to the structural and functional cardiac conditions already discussed, numerous systemic metabolic aberrations may affect the ECG, including electrolyte abnormalities and acid-base disorders, as well as systemic hypothermia.^{53,54,79}

Calcium

Hypercalcemia and hypocalcemia predominantly alter the action potential duration. An increased extracellular calcium concentration shortens the ventricular action potential duration by shortening phase 2 of the action potential. By contrast, hypocalcemia prolongs phase 2 of the action potential. These cellular changes correlate with abbreviation and prolongation of the QT interval (ST-segment portion) with hypercalcemia and hypocalcemia, respectively (**Fig. 12-48**). Severe hypercalcemia (e.g., serum Ca²⁺ >15 mg/dL) also can be associated with decreased T wave amplitude, sometimes with T wave notching or inversion. Hypercalcemia sometimes produces a high takeoff of the ST segment in leads V₁ and V₂ and can thus simulate acute ischemia (see **Table 12-11**).

Potassium

Hyperkalemia is associated with a distinctive sequence of ECG changes (**Fig. 12-49A**). The earliest effect usually is narrowing and

FIGURE 12-47 **Top**, Digitalis effect. Digitalis glycosides characteristically produce shortening of the QT interval with a scooped or downsloping ST-T complex. **Bottom**, Digitalis effect in combination with digitalis toxicity. The underlying rhythm is atrial fibrillation. A group beating pattern of QRS complexes with shortening of the R-R intervals is consistent with nonparoxysmal junctional tachycardia with probable exit (atrioventricular Wenckebach) variant. ST-segment depression and scooping (lead V_6) are consistent with the digitalis effect, although ischemia or LVH cannot be excluded. These ECG findings are strongly suggestive of digitalis excess; the serum digoxin level was higher than 3 ng/mL. Note that digitalis effect (ST-T changes) does not necessarily imply digitalis toxicity. Most patients with digitalis toxicity, however, do show digitalis effect on the ECG. (**Top**, From Goldberger AL, Goldberger ZD, Shvilkin A: *Goldberger's Clinical Electrocardiography: A Simplified Approach*. 8th ed. Philadelphia, Saunders, 2012.)

FIGURE 12-48 Prolongation of the QT interval (ST-segment portion) is typical of hypocalcemia. Hypercalcemia may cause abbreviation of the ST segment and shortening of the QT interval. (From Goldberger AL, Goldberger ZD, Shvilkin A: *Goldberger's Clinical Electrocardiography: A Simplified Approach*. 8th ed. Philadelphia, Saunders, 2012.)

peaking (or tenting) of the T wave. The QT interval is shortened at this stage, associated with decreased action potential duration. Progressive extracellular hyperkalemia reduces atrial and ventricular resting membrane potentials, thereby inactivating sodium channels, which decreases V_{max} and conduction velocity. The QRS begins to widen

and P wave amplitude decreases. PR interval prolongation can occur, followed sometimes by second- or third-degree atrioventricular block. Complete loss of P waves may be associated with a junctional escape rhythm or so-called *sinoventricular rhythm*. In the latter instance, sinus rhythm persists with conduction between the sinoatrial and atrioventricular nodes and occurs without producing an overt P wave. Moderate to severe hyperkalemia occasionally induces ST elevations in the right precordial leads (V_1 and V_2), simulating an ischemic current of injury or Brugada-type patterns. Even severe hyperkalemia, however, can be associated with atypical or nondiagnostic ECG findings. Very marked hyperkalemia leads to eventual asystole, sometimes preceded by a slow undulatory (or *sine wave*) ventricular flutterlike pattern. The ECG triad of (1) peaked T waves (from hyperkalemia), (2) QT prolongation (from hypocalcemia), and (3) LVH (from hypertension) is strongly suggestive of chronic renal failure (see [Chapter 88](#)).

Electrophysiologic changes associated with hypokalemia, by contrast, include hyperpolarization of myocardial cell membranes and increased action potential duration. The major ECG manifestations are ST depression with flattened T waves and increased U wave prominence ([Fig. 12-49B](#)). The U waves can exceed the amplitude of T waves. In clinical practice, distinguishing T waves from U waves can be difficult or impossible from the surface ECG. Indeed, apparent U waves in hypokalemia and other pathologic settings may actually be part of T waves whose morphology is altered by the effects of voltage gradients between M, or midmyocardial, cells, and adjacent myocardial layers.^{10,79} The prolongation of repolarization with hypokalemia, as part of an acquired long QT(U) syndrome, predisposes affected patients to the development of torsades de pointes. Hypokalemia also predisposes to tachyarrhythmias from digitalis.

Magnesium

Specific electrocardiographic effects of mild to moderate isolated abnormalities in magnesium ion concentration are not well characterized. Severe hypermagnesemia (serum $Mg^{2+} > 15$ mEq/L) can cause atrioventricular and intraventricular conduction disturbances that may culminate in complete heart block and cardiac arrest. Hypomagnesemia usually is associated with hypocalcemia or hypokalemia. Hypomagnesemia can potentiate certain digitalis toxic arrhythmias, and the role of magnesium deficiency in the pathogenesis and treatment of the acquired long QT(U) syndrome with torsades de pointes is discussed in [Chapters 32 and 37](#).

Other Factors. Isolated hyponatremia or hyponatremia does not produce consistent effects on the ECG. Acidemia and alkalemia are often associated with hyperkalemia and hypokalemia, respectively.

Systemic hypothermia may be associated with the appearance of a distinctive convex elevation at the junction (J point) of the ST segment and QRS complex (*J wave* or *Osborn wave*)^{10,79} (Fig. 12-50). The cellular mechanism of this type of pathologic J wave appears to be related to an epicardial-endocardial voltage gradient associated with the localized appearance of a prominent epicardial action potential notch.

Nonspecific QRS and ST-T Changes

Low QRS voltage is said to be present when the total amplitude of the QRS complexes in each of the six extremity leads is 0.5 mV or less or 1.0 mV or less in leads V₁ through V₆. Low QRS voltage, as described earlier, can be caused by a variety of mechanisms, including increased insulation of the heart by air (chronic obstructive pulmonary disease) or adipose tissue (obesity); replacement of myocardium, for example,

by fibrous tissue (ischemic or nonischemic cardiomyopathy), amyloid, or tumor; or to short-circuiting (shunting) effects resulting from low resistance of fluids (especially with pericardial or pleural effusions, or anasarca). The combination of relatively low limb voltage (QRS voltage <0.8 mV in each of the limb leads), relatively prominent QRS voltage in the chest leads (SV₁ or SV₂ + RV₅ or RV₆ >3.5 mV), and slow R wave progression (R wave less than the S wave amplitude in V₁ through V₄) has been reported as a relatively specific but not sensitive sign of dilated-type cardiomyopathies (sometimes referred to as the ECG congestive heart failure triad).⁵²

Ventricular repolarization is particularly sensitive to the effects of many factors in addition to ischemia (e.g., postural changes, meals, drugs, hypertrophy, electrolyte and metabolic disorders, central nervous system lesions, infections, pulmonary diseases) that can lead to a variety of nonspecific ST-T changes. The term usually is applied to slight ST-segment depression or T wave inversion or to T wave flattening without evident specific cause. Care must be taken not to overinterpret such changes, especially in subjects with a low previous probability of heart disease. At the same time, subtle repolarization abnormalities can be markers of coronary or hypertensive heart disease or other types of structural heart disease; these probably account for the association of relatively minor but persistent nonspecific ST-T changes with increased cardiovascular mortality in middle-aged men and women.⁸⁰

Alternans Patterns

The term *alternans* applies to conditions characterized by the sudden appearance of a periodic beat-to-beat change in some aspect of cardiac electrical or mechanical behavior. These abrupt (period-doubling) changes (AAAA > ABAB pattern) are reminiscent of a generic class of patterns observed in perturbed nonlinear control systems. Many different examples of electrical alternans have been described clinically, and a number of others have been reported in the laboratory. Most familiar is total electrical alternans with sinus tachycardia, a specific but not highly sensitive marker of pericardial effusion with tamponade physiology (Fig. 12-51) (see Chapter 71). This finding is associated with an abrupt transition from a 1:1 to a 2:1 pattern in the "to-and-fro" swinging motion of the heart in the effusion (see Fig. 15-72).

Other alternans patterns have primary electrical rather than mechanical causes. QRS (and sometimes R-R) alternans may occur with a number of different types of supraventricular tachycardias.⁸¹ Alternans has long been recognized as a marker of electrical instability in cases of acute ischemia, in which it may precede ventricular tachyarrhythmia (see Fig. 12-37). Considerable interest continues to be directed at the detection of microvolt T wave (or ST-T) alternans as a noninvasive marker for increased risk of ventricular tachyarrhythmias in patients with chronic heart disease (see Chapter 34).⁸²⁻⁸⁴ Similarly, T-U wave alternans (Fig. 12-52) may be a marker of imminent risk of torsades de pointes in hereditary or acquired long QT syndromes.

FIGURE 12-49 Electrocardiographic changes in hyperkalemia (A) and hypokalemia (B). A, On day 1, at a K⁺ level of 8.6 mEq/liter, the P wave is no longer recognizable and the QRS complex is diffusely prolonged. Initial and terminal QRS delays are characteristic of K⁺-induced intraventricular conduction slowing and are best illustrated in leads V₂ and V₆. On day 2, at a K⁺ level of 5.8 mEq/liter, the P wave is recognizable, with a PR interval of 0.24 second; the duration of the QRS complex is approximately 0.10 second, and the T waves are characteristically "tented." B, On day 1, at a K⁺ level of 1.5 mEq/liter, the T and U waves are merged. The U wave is prominent and the QU interval is prolonged. On day 4, at a K⁺ level of 3.7 mEq/liter, the tracing is normal. (A, B, Courtesy Dr. C. Fisch.)

FIGURE 12-50 Systemic hypothermia. The arrowheads (leads V₃ through V₆) point to the characteristic convex J waves, termed Osborn waves. Prominent sinus bradycardia is also present.

FIGURE 12-51 Total electrical alternans (P-QRS-T) caused by pericardial effusion with tamponade. This finding, particularly in concert with sinus tachycardia and relatively low voltage, is a highly specific, although not sensitive, marker of cardiac tamponade.

FIGURE 12-52 The QT(U) interval is prolonged (approximately 600 milliseconds) with TU wave alternans. The tracing was recorded in a patient with chronic renal disease shortly after dialysis. This type of repolarization alternans may be a precursor to torsades de pointes. (Courtesy Dr. C. Fisch.)

CLINICAL ISSUES IN ELECTROCARDIOGRAPHIC INTERPRETATION

The clinical effectiveness of the ECG as a diagnostic tool depends on factors such as the indications for the procedure, proper recording technique, and the skills of the interpreter of the ECG.

Indications for an Electrocardiogram

Relatively limited attention has been paid to the indications for an ECG, probably because of its seeming simplicity, safety, and low cost. However, the cumulative expense of low-cost tests performed at high volume is significant, and the potential risks (and costs) to the patient of missed (false-negative) or false (false-positive) diagnoses of cardiac disease can be substantial. Recommendations for performing ECGs have been proposed by various organizations; these are described and discussed in the section at the end of this chapter.

Although most efforts have focused on preventing overuse, the ECG may be underused in other important clinical situations. For example, more than one third of patients evaluated for angina pectoris in outpatient settings do not have an ECG recorded,⁸⁵ and only one fourth of patients with ST-segment elevation myocardial infarction transported to emergency departments have a prehospital ECG, leading to delays in revascularization procedures.⁸⁶

Technical Errors and Artifacts

Technical errors can lead to clinically significant diagnostic mistakes. Artifacts that may interfere with interpretation can come from movement of the patient, poorly secured electrodes, electrical disturbances related to current leakage and grounding failure, or external interference from electrical sources such as stimulators or cauteries. Electrical artifacts can simulate life-threatening arrhythmias (Fig. 12-53), and excessive body motion can cause excessive baseline wander that may simulate or obscure ST-segment shifts of myocardial ischemia or injury.

Misplacement of one or more electrodes is a common cause for errors in interpretation of the ECG. Many limb lead switches produce electrocardiographic patterns that can aid in their identification.⁸⁷ Reversal of the two arm electrodes, for example, results in an inverted P and QRS waveforms in lead I but not in lead V₆, two leads that would normally be expected to have similar polarities. Other lead misplacements are not as obvious. Similarly, ECGs recorded from electrode subsets such as used for exercise testing or intensive care settings are significantly different from those recorded using standard electrode sets and should not be used for diagnostic purposes.¹

Errors in placement of the precordial electrodes is common. In one study, only 49% of physicians and 16% of cardiologists were able to correctly identify the location of the V₁ electrode.⁸⁸ The most common errors are placing the V₁ and V₂ electrodes in the second or third rather than in the fourth intercostal space and placing the V₄ to V₆ electrodes too high on the lateral chest. Placing the right precordial electrodes too high on the chest can yield patterns that mimic those of anterior myocardial infarction (delayed R wave progression) or an intraventricular conduction delay (e.g., rSr' patterns in lead V₁).

Another common technical error is recording the ECG with non-standard high- and low-pass filter settings. Increasing the low-frequency cutoff to reduce baseline wander and respiratory effects can produce a range of artifactual ST-segment abnormalities. Lowering the high-frequency cutoff to reduce motion and tremor artifacts reduces R wave amplitudes and Q wave measurements and decreases the accuracy of diagnoses of hypertrophy and infarction.¹

Other technical issues reflect characteristics of computerized systems. Clinically relevant differences in measurements may be

FIGURE 12-53 Artifacts simulating serious arrhythmias. **A**, Motion artifact mimicking ventricular tachycardia. Partly obscured normal QRS complexes (arrowheads) can be seen with a heart rate of approximately 100 beats/minute. **B**, Parkinsonian tremor causing baseline oscillations mimicking atrial fibrillation. The regularity of QRS complexes may provide a clue to the source of this artifact.

reported by systems from different manufacturers and by different software versions from the same manufacturer.¹ Other differences result from variation in the signals used for computerized interpretation and for graphic display. For example, intervals measured by eye may be significantly shorter than those reported by software programs, because the software determines the interval from an overlay of patterns from all leads, whereas manual methods typically rely on the analysis of the waveform from a single lead. Differences in intervals, such as the duration of the Q wave or the QRS complex, may be sufficient to alter the diagnosis of conduction defects and infarction.

Reading Competency

Developing and maintaining competency in interpretation of the ECG are critical to successful clinical practice. The Accreditation Council for Graduate Medical Education and the ACC recommend supervised and documented interpretation of a minimum of 3500 ECGs covering a broad spectrum of diagnoses and clinical settings over a 3-year training period for cardiology fellows,⁸⁹ although the actual adequacy of training and the level of competency of trainees remain limited.^{90,91} The challenge of adequate training is compounded by the number of physician specialties with various modes and intensity of training in interpretation of ECGs.

Errors in interpreting ECGs are common and may be increasing in frequency. In one study, less than half of test ECGs with commonly encountered abnormalities were correctly interpreted by first-year internal medicine residents in a university-based training program.⁹¹ Another study reported accurate overreading of only 74% of erroneous computer-based interpretations by cardiologists.⁹²

Studies assessing the accuracy of routine interpretations have demonstrated common errors can lead to clinical mismanagement, including failure to identify and triage patients with acute myocardial ischemia. In a study of patients with acute myocardial infarction who were eligible for but did not receive revascularization, an ECG interpretation that did not correctly identify ST-segment elevation was the cause for omission of revascularization in 34%.⁹³ A set of common pitfalls in the ECG diagnosis of myocardial infarction has recently been published.⁹⁴

A final issue concerns overreliance on computerized interpretations. Although computerized diagnostic algorithms have become more accurate and serve as important adjuncts to the clinical interpretation of ECGs, such measurements and diagnoses currently are not sufficiently accurate to be relied on in critical clinical environments without expert review. Overall error rates in interpreting

abnormal ECGs may be as high as 16%,⁹⁵ with highest error rates for rhythm abnormalities.

Various tools are available to assess and improve proficiency. Programs such as the ECG Self-Assessment Program of the ACC are useful for identifying knowledge levels of proficiency and areas of specific weakness. A number of websites feature ECGs for self-assessment and clinical instruction. ECG Wave-Maven (<http://ecg.bidmc.harvard.edu>) provides free access to more than 400 case studies of ECGs, with answers and multimedia adjuncts.

FUTURE PERSPECTIVES

Clinical electrocardiography represents a mature cardiovascular methodology based on extensive electrophysiologic and clinical correlates that have been elaborated

over more than a century of study. This historic richness of the surface ECG as a source of basic physiologic and clinical information continues to support the expectation of future unanticipated areas for exploration and discovery.

Several areas for expanded knowledge and clinical relevance may be identified. Although recent and future advances in imaging techniques provide a more direct assessment of cardiac structural abnormalities than that afforded by the ECG, the ECG uniquely provides information about the electrical properties of the heart. Recent advances in biomedical engineering and technology, clinical therapeutics, and basic science suggest approaches to expand this value. Some advances such as development of optimal lead systems for ECG recording and diagnostic criteria stratified for race and sex may improve the value of the standard ECG. Other advances represent major changes in approach. Examples are advanced mathematical analysis of body surface potentials, such as those that estimate direct cardiac potentials from surface recordings (see Chapter 34), and the assessment of genomic and biomarker patterns that permit more direct understanding of the abnormal physiology underlying electrocardiographic patterns (see Chapters 9 and 33). Progress in refining current diagnostic criteria and in discovering new ones will be greatly fostered by the availability of meticulously annotated, open-access databases of high resolution, digital ECGs with detailed clinical correlates, including echocardiogram and other imaging studies, and outcome measures if available.

GUIDELINES

Electrocardiography

David M. Mirvis and Ary L. Goldberger

Indications for electrocardiography can be considered for several different subpopulations—persons with known heart disease, those with suspected heart disease or at high risk for heart disease, and those without evidence of heart disease. In addition, more specific recommendations have been proposed for the use of electrocardiography in special groups, including preoperative patients, persons with dangerous occupations, athletes, and people taking medications with electrophysiologic effects.

The most widely cited guidelines were published jointly by the American College of Cardiology (ACC) and the American Heart Association (AHA) in 1992¹ and later expanded or modified.^{2,3} These are summarized in **Tables 12G-1 through 12G-3**. The ACC, the AHA, and other professional groups also have published guidelines for use in specific populations and clinical settings. More recently, some specific recommendations have been reviewed and challenged.

Patients with Known Cardiovascular Disease

The ACC/AHA guidelines¹ support the use of ECGs in the baseline evaluation of all patients with known cardiovascular disease, when

important clinical changes occur, for following the course of disease, and for the evaluation of response to therapies likely to produce ECG changes (see **Table 12G-1**). Thus, in patients with known cardiac disease, ECGs are warranted as part of a baseline examination; after initiating therapy known to produce ECG changes that correlate with therapeutic responses, progression of disease, or adverse effects; for intermittent follow-up evaluations for investigation of changes in signs or symptoms such as syncope, chest pain, and extreme fatigue or relevant laboratory findings; and after significant intervals (usually 1 year or longer) in the absence of clinical changes. Follow-up ECGs are not considered appropriate for patients with mild chronic cardiovascular conditions that are not deemed likely to progress (e.g., mild mitral valve prolapse). ECGs at each visit are considered inappropriate for patients with stable heart disease who are seen frequently (e.g., within 4 months) and have no evidence of clinical change.

Patients Suspected of Having Cardiovascular Disease

In patients suspected of having cardiac disease or those at high risk for cardiac disease, an ECG is appropriate as part of an initial evaluation in the presence of signs or symptoms suggesting cardiac disease; in patients with important risk factors such as cigarette smoking, diabetes mellitus, peripheral vascular disease, or a family history of cardiac disease; during therapy with cardioactive medications; and during follow-up if clinical events develop or at prolonged intervals if clinically stable (see **Table 12G-2**). In follow-up evaluation of patients at increased risk for heart disease, ECGs every 1 to 5 years

TABLE 12G-1 ACC/AHA Guidelines for Electrocardiography in Patients with Known Cardiovascular Disease or Dysfunction*

INDICATION	CLASS I (INDICATED)	CLASS II (EQUIVOCAL)	CLASS III (NOT INDICATED)
Baseline or initial evaluation	All patients	None	None
Response to therapy	Patients in whom prescribed therapy is known to produce changes in the ECG that correlate with therapeutic responses or progression of disease Patients in whom prescribed therapy may produce adverse effects that may be predicted from or detected by changes in the ECG	None	Patients receiving pharmacologic or nonpharmacologic therapy not known to produce changes in the ECG or to affect conditions that may be associated with such changes
Follow-up evaluation	Patients with a change in symptoms, signs, or laboratory findings related to cardiovascular status. Patients with an implanted pacemaker or antitachycardia device Patients with new signs or symptoms related to cardiovascular function Patients with cardiovascular disease such as the following, even in the absence of new symptoms or signs, after an interval of time appropriate for the condition or disease	None	Adult patients whose cardiovascular condition is usually benign and unlikely to progress (e.g., patients with asymptomatic mild mitral valve prolapse, mild hypertension, or premature contractions in absence of organic heart disease). Adult patients with chronic stable heart disease seen at frequent intervals (e.g., 4 months) and unexplained findings
Before surgery	All patients with known cardiovascular disease or dysfunction, except as noted under class II	Patients with hemodynamically insignificant congenital or acquired heart disease, mild systemic hypertension, or infrequent premature complexes in absence of organic heart disease	None

*Based on published recommendations of the AHA,¹⁻³ ACC,¹⁻³ and USPSTF.⁴

TABLE 12G-2 ACC/AHA Guidelines for Electrocardiography in Patients Suspected of Having or at Increased Risk for Cardiovascular Disease or Dysfunction*

SETTING	CLASS I (APPROPRIATE)	CLASS II (EQUIVOCAL)	CLASS III (INAPPROPRIATE)
Baseline or initial evaluation	All patients suspected of having or being at increased risk for cardiovascular disease Patients who may have used cocaine, amphetamines, or other illicit drugs known to have cardiac effects Patients who may have received an overdose of a drug known to have cardiac effects	None	None
Response to therapy	To assess therapy with cardioactive drugs in patients with suspected cardiac disease To assess response to administration of any agent known to result in cardiac abnormalities or abnormalities on the ECG (e.g., antineoplastic drugs, lithium, antidepressant agents)	To assess response to administration of any agent known to alter serum electrolyte concentration	To assess response to administration of agents known not to influence cardiac structure or function
Follow-up examination, once	Presence of any change in clinical status or laboratory findings suggesting interval development of cardiac disease or dysfunction Periodic follow-up examination of patients (e.g., every 1 to 5 years) known to be at increased risk for cardiac disease Follow-up evaluation of patients after resolution of chest pain	None	Follow-up ECGs more often than yearly for patients who remain clinically stable, not at increased risk for development of cardiac disease, and not demonstrated to have cardiac disease with previous studies
Before surgery	Patients with ≥ 1 risk factor undergoing vascular or other high-risk surgery, based on individual clinical assessments	Patients with ≥ 1 risk factors undergoing intermediate-risk procedures	Asymptomatic persons undergoing low-risk procedures

*Based on published recommendations of the AHA,¹⁻³ ACC,¹⁻³ and USPSTF.⁴

TABLE 12G-3 ACC/AHA Guidelines for Electrocardiography in Patients with No Apparent or Suspected Heart Disease or Dysfunction*

SETTING	CLASS I (APPROPRIATE)	CLASS II (EQUIVOCAL)	CLASS III (INAPPROPRIATE)
Baseline or initial evaluation	Before administration of pharmacologic agents known to be associated with a high incidence of cardiovascular effects (e.g., antineoplastic agents) Before exercise stress testing People of any age in special occupations that require very high cardiovascular performance (e.g., fire fighters, police officers) or whose cardiovascular performance is linked to public safety (e.g., pilots, air traffic controllers, critical process operators, bus or truck drivers, railroad engineers)	Initial evaluation of patients with risk factors such as diabetes and hypertension Preparticipation examination of competitive athletes	Routine screening or baseline ECG in asymptomatic, low-risk persons
Response to therapy	To evaluate patients in whom prescribed therapy (e.g., doxorubicin) is known to produce cardiovascular effects	None	To assess treatment known not to produce any cardiovascular effects
Follow-up	To evaluate interval changes in symptoms or signs	None	To evaluate asymptomatic adults who have had no interval change in symptoms, signs, or risk factors
Before surgery	Patients being evaluated as donor for heart transplantation or as recipient of noncardiopulmonary transplant	Patients undergoing vascular or other high-risk procedures	Asymptomatic persons undergoing low-risk procedures

*Based on published recommendations of the AHA,¹⁻³ ACC,¹⁻³ and USPSTF.⁴

are considered appropriate, but routine ECGs more frequently than yearly are not supported for patients who remain clinically stable.

Patients Without Known or Suspected Cardiovascular Disease

It has become common practice to include an ECG as part of routine health examinations in patients without known disease or significant risk factors, and on any admission to a hospital. Little evidence is available to support these practices, and the recommendations for routine clinical screening by numerous organizations, including most recently the United States Preventive Services Task Force (USPSTF),⁴ do not include a routine ECG in these settings. Although several ECG

findings do indicate an increased risk of a future cardiovascular event, as described in this chapter, the overall sensitivity and specificity of the ECG for identifying individual patients who will have future events are low. There is also inadequate evidence that adding an ECG to the standard risk assessment approach based on history and physical examination improves risk stratification or alters the risk management approach. In addition, the consequences of high rates of false-positive results, including unnecessary, expensive and potentially hazardous noninvasive and invasive diagnostic testing, over-treatment, and labeling, especially in populations with a low prevalence of disease, are significant.

Based on these factors, the Task Force⁴ concluded that for persons with low risk of events ($<10\%$ likelihood within 10 years) based on

other risk factor analyses, the possible harm of routine ECGs in this population outweighs the possible benefits. Hence a routine ECG in this group is not warranted and its use is discouraged. In patients with higher risks, the Task Force concluded that the existing data are insufficient to make a definitive recommendation about the relative benefits and risks of a routine ECG.

The 1992 ACC/AHA guidelines indicated that ECGs are considered appropriate screening tests in patients without apparent or suspected heart disease who are 40 years of age or older. More recent guidelines from these organizations² state that a routine ECG “is reasonable” for patients with diabetes or hypertension and “may be considered” for other patients (see Table 12G-3).

Special Populations

Persons with Dangerous Occupations

Recommendations for screening of persons with dangerous jobs or jobs that place other people at risk—for example, airline pilots and bus drivers—also are controversial. Although no specific data defining the value of routine screening are available, some groups, including the USPSTF⁴ and the AHA,² recognize the potential for benefit in relation to the possible risk to others.

Preoperative Evaluation

The common practice of routinely recording an ECG before noncardiac surgery in patients without other indications also has been challenged. Most, although not all, studies have documented the limited value of the routine preoperative ECG in identifying patients with coronary artery disease and in predicting postoperative outcomes. Thus the AHA³ and other professional societies recommend a routine ECG for patients with one or more risk factors undergoing vascular surgery and for patients with known coronary, peripheral or cerebrovascular disease undergoing intermediate-risk procedures. It may be reasonable in patients without risk factors undergoing vascular procedures or those with risk factors who are undergoing vascular or intermediate-risk procedures.³ These groups do not, however, recommend ECGs in asymptomatic persons undergoing low-risk procedures.

Similarly, the American Society of Anesthesiologists Task Force on Preanesthesia Evaluation recommended that the decision to perform preoperative ECGs be based on the clinical features of individual patients, rather than routinely incorporating this test into the presurgical regimen.⁵ Factors influencing the decision to perform an ECG include age older than 65 years, presence of known cardiac or respiratory disease, specific type of surgery planned, and the presence of major cardiac risk factors. A study by Correll and co-workers⁶ suggested that preoperative ECGs may be appropriate in patients 65 years of age or older or in those with a history of heart failure, angina pectoris, myocardial infarction, severe valve disease, or hyperlipidemia.

Screening of Athletes

Routine ECG screening of competitive athletes younger than 35 years of age remains controversial.^{7,8} Both the European Society of Cardiology⁹ and the International Olympic Committee recommend including

the ECG as part of preparticipation medical assessment. These recommendations are based on high sensitivity of the ECG for detecting the most common underlying causes of athlete deaths, such as hypertrophic cardiomyopathy and the long-QT interval syndromes, and the experience of the 30-year national screening program in Italy to prospectively identify these abnormalities and to reduce the occurrence of sudden death by facilitating the disqualification of high-risk affected persons.¹⁰

By contrast, the AHA does not recommend routine ECG screening.¹¹ Reasons for this standpoint include the limited and conflicting data on the benefits, the significant false-positive rate leading to the inappropriate disqualification of many athletes, and the high cost and the lack of an organized system for performing ECG recordings in the large number of athletes. Rather, the AHA recommends an ECG only if suggestive abnormalities are revealed in the personal and family history or found on physical examination. For older persons seeking to engage in competitive sports, a standard 12-lead ECG is recommended as part of a routine evaluation for all athletes older than 40 years of age.¹² No conclusive data exists on the value of ECG screening for recreational athletes of any age.

Cardioactive Drug Administration

The role of the ECG as a baseline examination and in follow-up evaluation of patients taking drugs (see earlier) with potential cardioactive effects, especially QT(U) interval prolongation, remains poorly defined and, in some cases, controversial. Drugs that have ECG effects include antiarrhythmic agents, methadone, and tricyclic antidepressants and other psychotropic agents.

REFERENCES, 173**GUIDELINES, 174**

Exercise electrocardiographic testing is among the most fundamental and widely used tests for the evaluation of patients with cardiovascular disease (CVD). It is easy to administer, perform, and interpret; it is flexible and adaptable; and it is reliable, inexpensive, and readily available in hospital or practice settings. The exercise test has been used by clinicians for more than half a century, and its durability can be attributed to its evolution over time. Initially developed to detect the presence of myocardial ischemia secondary to coronary artery disease (CAD), the exercise electrocardiogram (ECG) is now recognized for its power in predicting prognosis. Exercise test variables beyond the ST segment yield important information, particularly when used in combination with clinical information, to predict outcomes and guide therapy in a broad range of individuals—from the healthy to those crippled by heart disease. Emerging applications of exercise electrocardiography have demonstrated its usefulness in the evaluation and management of patients with a wide variety of cardiovascular conditions, including valvular heart disease, congenital heart disease, genetic cardiovascular conditions, arrhythmias, and peripheral arterial disease (PAD). When used appropriately with adjunctive modalities to measure gas exchange and ventilation or with imaging techniques such as echocardiography or nuclear perfusion imaging (see Chapters 14 and 16), the power of the exercise ECG is greatly enhanced. The exercise ECG is the clinician's beacon that can guide optimal care for a great majority of patients with known or suspected CVD. This chapter provides a detailed foundation of information on the exercise ECG. Other chapters in this text address adjunctive imaging techniques and further discuss the use of exercise testing in patients with specific cardiovascular conditions.

PHYSIOLOGY OF EXERCISE TESTING**Total-Body Oxygen Uptake**

Exercising muscles require energy to contract and relax. Most of this energy is derived from oxidative metabolism to generate adenosine triphosphate; hence energy requirements at rest and for any given amount of physical activity (work rate) can be estimated from measurements of total-body oxygen uptake ($\dot{V}O_2$). The Fick equation demonstrates that $\dot{V}O_2$ is equal to the product of cardiac output and oxygen extraction at the periphery (i.e., arteriovenous oxygen difference). $\dot{V}O_2$ is easily expressed in multiples of resting oxygen requirements (metabolic equivalents [METs]), with 1 MET being

resting energy expenditure and defined as approximately 3.5 mL oxygen/kg body weight/min. This convenient system indexes the amount of energy used during any given physical activity against that used at rest. Accordingly, 5-MET activity requires five times the energy expenditure at rest. $\dot{V}O_{2\max}$ is the peak oxygen uptake achieved during performance of the highest level of dynamic exercise involving large muscle groups and by definition cannot be exceeded despite increases in work rate. It is related to age, sex, heredity, exercise habits, and cardiovascular status. Cardiac output can increase as much as four to six times resting levels in the upright position. Maximum cardiac output is the result of a twofold to threefold increase in heart rate from resting levels and an increase in stroke volume. Stroke volume in healthy persons generally plateaus at 50% to 60% of $\dot{V}O_{2\max}$. Oxygen extraction at the periphery can increase as much as threefold, and the maximum arteriovenous oxygen difference has a physiologic limit of 15 to 17 mL oxygen/100 mL blood. During clinical exercise testing, patients are prompted to exercise not until they attain $\dot{V}O_{2\max}$ but rather to the $\dot{V}O_2$ that is attained during symptom-limited, maximum tolerated exercise—this level is termed the $\dot{V}O_2$ peak.¹

Effects of Exercise on Myocardial Oxygen Demand and Supply Relationships

Myocardial ischemia occurs when the supply of oxygenated blood to myocardial cells is inadequate to meet demands. Many factors affect the delicate balance of supply and demand (Fig. 13-1). Exercise testing is performed to stress these relationships and observe the physiologic responses that ensue. This enables the clinician to not only assess for the development of myocardial ischemia but, importantly, to also evaluate at what level of myocardial oxygen demand and physical activity (work rate) it occurs.¹

Myocardial Oxygen Demand. Myocardial oxygen demand is related to heart rate, blood pressure, left ventricular contractility (myocardial shortening per beat), and left ventricular wall stress. The latter is related to left ventricular pressure, wall thickness, and cavity size. Changes in any of these interdependent factors can affect myocardial need for oxygenated blood. Of these parameters, heart rate and blood pressure are the easiest to measure and monitor. The product of heart rate and systolic blood pressure, termed the *rate-pressure product*, is a reliable index of myocardial oxygen demand and can be readily assessed clinically.

FIGURE 13-1 Physiologic responses to acute exercise. See text for details. HR = heart rate; SV = stroke volume.

During acute endurance (high-repetition/low-resistance) exercise (e.g., walking or cycling), cardiac output rises in response to the metabolic needs of the exercising muscles (estimated by measured $\dot{V}O_2$). Diminution of vagal tone and a rise in sympathetic tone lead to an increase in heart rate and left ventricular contractility. Stroke volume also rises because of increases in venous return of blood from exercising muscles, and blood flow is redistributed from the renal, splanchnic, and cutaneous circulation to the exercising muscles. Accumulation of metabolites in the actively contracting muscles causes vasodilation of muscle arterioles, which increases skeletal muscle blood flow up to four times that of resting levels and results in a reduction in aortic outflow impedance. This, in turn, allows more complete systolic ejection, thereby further increasing stroke volume. Systolic blood pressure increases mostly because of the rise in cardiac output, whereas diastolic blood pressure either remains constant or falls as a result of the reduction in vascular resistance. The size and location of the exercising muscle groups will have different effects on the hemodynamic response to exercise. Dynamic arm exercise elicits higher heart rate and blood pressure responses at any given work rate than does dynamic leg exercise. Arm work yields differences in sympathetic output, peripheral vasodilation, venous return, and metabolic requirements, which are influenced not only by the exercising muscle mass but also by the stabilizing muscles recruited during arm exercise.¹

Resistance (low-repetition/high-load) exercise (e.g., weightlifting) is not generally used during graded exercise testing but may be used in work simulation testing or exercise training regimens. This type of exercise generates an increased sympathetic response leading to an increase in heart rate; however, venous return, especially during straining, may decrease. Hence the rise in cardiac output is relatively small in comparison to that achieved with endurance exercise and is primarily due to increases in heart rate. Muscle contraction during resistance exercise generates compressive force on muscle capillaries that leads to elevated peripheral resistance. This rise in vascular resistance coupled with an increase in cardiac output yields an increase in both systolic and diastolic pressure. Elevations in systolic blood pressure from rest to exercise are proportionally greater than the elevations in heart rate during resistance exercise than during endurance exercise. Therefore both endurance exercise and resistance exercise

increase myocardial oxygen demand because of increases in heart rate, blood pressure, left ventricular contractility, and left ventricular wall stress (the latter caused by increases in left ventricular pressure and volume during exercise).¹

Myocardial Oxygen Supply. Coronary blood flow increases during exercise in response to neurohumoral stimulation (primarily sympathetic beta receptor stimulation) and as a result of the release of endothelial substances, including nitric oxide. In healthy persons during acute exercise, coronary arteries dilate and coronary blood flow rises in response to the increases in myocardial oxygen demand. Most commonly, coronary flow is compromised as a result of atherosclerotic plaque within the lumen of the coronary artery (see Chapter 49). Plaque may cause minimal stenosis or complete occlusion of the artery. Several factors influence the significance of a given luminal stenosis, including the degree of luminal obstruction, the length of the obstruction, the number and size of functioning collateral vessels, the magnitude of the muscle mass supplied, the shape and dynamic properties of the stenosis, and the autoregulatory capacity of the vascular bed. In general, a 50% to 70% reduction in luminal diameter will impair peak reactive hyperemia, whereas 90% or greater stenosis will reduce resting flow. However, exercise stimulates local changes in vasomotor tone as a result of neuromodulation, endothelial dysfunction, and local factors, and these changes can further influence the supply of oxygenated blood to the myocardium. Atherosclerotic arteries often fail to dilate and may actually constrict with exercise, thus further reducing the supply of blood in the setting of increased demand.¹

TECHNICAL ASPECTS OF EXERCISE TESTING

Subject Preparation Patient Assessment

It is important to assess the patient before performing the exercise test to evaluate the indications for the test, the appropriateness of the specific test that has been ordered to answer the question posed, the

TABLE 13-1 Contraindications to Exercise Testing

Absolute Contraindications
Acute myocardial infarction (within 2 days)
High-risk unstable angina
Uncontrolled cardiac arrhythmia with hemodynamic compromise
Active endocarditis
Symptomatic severe aortic stenosis
Decompensated heart failure
Acute pulmonary embolism or pulmonary infarction
Acute myocarditis or pericarditis
Physical disability precluding safe and adequate testing
Relative Contraindications
Known left main coronary artery stenosis
Moderate aortic stenosis with uncertain relationship to symptoms
Tachyarrhythmias with uncontrolled ventricular rates
Acquired complete heart block
Hypertrophic cardiomyopathy with a severe resting gradient
Mental impairment with limited ability to cooperate

From Fletcher GF, Ades PA, Kligfield P, et al: Exercise standards for testing and training: a scientific statement from the American Heart Association. *Circulation* 128:873, 2013.

TABLE 13-2 Patient Assessment for Exercise Testing

History
1. <i>Medical diagnoses and past medical history</i> —a variety of diagnoses should be reviewed, including CVD (known existing CAD, previous myocardial infarction, or coronary revascularization); arrhythmias, syncope, or presyncope; pulmonary disease, including asthma, emphysema, and bronchitis or recent pulmonary embolism; cerebrovascular disease, including stroke; PAD; current pregnancy; musculoskeletal, neuromuscular, and joint disease
2. <i>Symptoms</i> —angina; chest, jaw, or arm discomfort; shortness of breath; palpitations, especially if associated with physical activity, eating a large meal, emotional upset, or exposure to cold
3. <i>Risk factors for atherosclerotic disease</i> —hypertension, diabetes, obesity, dyslipidemia, smoking; if the patient is without known CAD, determine the pretest probability of CAD (see Table 13-11)
4. <i>Recent illness, hospitalization, or surgical procedure</i>
5. <i>Medication dose and schedule</i>
6. <i>Ability to perform physical activity</i>
Physical Examination
1. <i>Pulse rate and regularity</i>
2. <i>Resting blood pressure while sitting and standing</i>
3. <i>Auscultation of the lungs</i> , with specific attention to uniformity of breath sounds in all areas, particularly in patients with shortness of breath or a history of heart failure or pulmonary disease
4. <i>Auscultation of the heart</i> , particularly in patients with heart failure or valvular disease
5. <i>Examination related to orthopedic, neurologic, or other medical conditions</i> that might limit exercise

ability of the patient to perform exercise, and whether the patient has any contraindications to exercise testing (Table 13-1). Information from the medical history as provided by the patient, chart review, and the ordering provider and/or the patient's primary care physician or cardiologist can be most useful in this pretest evaluation. A brief physical examination that addresses the components outlined in Table 13-2 can also be helpful. A current standard resting 12-lead ECG is useful in assessing heart rate, rhythm, conduction abnormalities, and evidence of previous myocardial infarction and should be compared with the most recent previous ECG, if available.

Although diagnostic exercise tests in patients without known CAD are best performed by withholding cardioactive medications on the day of the test to better assess for an ischemic response, functional testing in patients with known CAD might best be performed with patients having taken their usual medications to evaluate the effects

of the medications on heart rate, blood pressure, symptoms, and ischemia during exercise. This issue is discussed again later in this chapter (see Medication Effects).

In patients with permanent cardiac pacemakers, it is important to obtain information from the patient's cardiologist regarding the type of pacemaker (single or dual chamber), programmed mode, rate responsiveness, and pacing heart rate limits before the test. Similarly, in patients with implantable cardioverter-defibrillators (ICDs), information regarding ICD rhythm detection and treatment algorithms should be obtained so that the peak heart rate during the exercise test is maintained at least 10 beats/min below the programmed heart rate threshold for antitachycardia pacing and defibrillation.² Additional details of patient assessment are provided elsewhere.¹

Symptom Rating Scales

Before exercising, patients should be made familiar with the symptom rating scales that might be used during testing. These are described further elsewhere² and may include the Borg Scale of Perceived Exertion.¹

Electrocardiographic Lead Systems

As the technology of exercise electrocardiographic testing has evolved, several different types of lead systems have been developed and used. Details regarding these lead systems, along with skin preparation techniques, are provided elsewhere.^{1,3} The importance of adequate skin preparation cannot be overstated, as this is essential to optimize the quality of the exercise ECG. To obtain a high-quality 12-lead ECG during testing, electrode placement on the torso is standard for routine testing. Torso electrodes are placed under the lateral aspect of the clavicles for the arm leads and on the lower end of the rib cage or high under the rib cage for the leg leads. A standard 12-lead ECG should be performed before placement of the torso limb leads because such lead placement may alter the inferior lead complexes and result in previous Q waves being either mimicked or hidden.

Exercise Test Modality and Protocols

The testing modality and protocol should be selected in accordance with the patient's estimated functional capacity based on age, estimated physical fitness from the patient's history, and underlying disease. Several exercise test protocols are available for both treadmill and stationary cycle ergometers. Patients who have low estimated fitness levels or are deemed to be at higher risk because of underlying disease (e.g., recent myocardial infarction, heart failure) should be tested with a less aggressive exercise protocol. Treadmill and cycle ergometers may use stepped or continuous ramp protocols. Work rate increments (stages) during stepped protocols can vary from 1 to 2.5 METs. Ramp protocols are designed with stages that are no longer than 1 minute and for the patient to attain peak effort within 8 to 12 minutes. Accordingly, ramp protocols must be individualized and selected to accommodate the patient's estimated exercise capacity. Because there are no widely published or standard sets of ramp protocols, individual exercise testing laboratories usually develop their own customized protocols that accommodate a wide range of fitness levels. Examples of such protocols are shown in Table 13-3.^{4,5} A variety of treadmill and cycle ergometer testing protocols are provided in detail by the American College of Sports Medicine (ACSM).²

Exercise tests may be submaximal or maximal relative to the patient's effort. In addition to common indications for stopping the exercise test (Table 13-4), submaximal exercise testing has a predetermined endpoint often defined as a peak heart rate (e.g., 120 beats/min or 70% of predicted maximum heart rate) or an arbitrary MET level (e.g., 5 METs). Submaximal tests are used in patients early after myocardial infarction before discharge from the hospital because they can provide prognostic information to guide management. They can also be useful in the evaluation of a patient's ability to engage in daily activities after discharge and in addition serve as a baseline for cardiac rehabilitative exercise therapy (see the later section Physical Activity and Exercise Prescription). Symptom-limited tests are

TABLE 13-4 Indications for Terminating an Exercise Test

Absolute Indications
ST elevation (>1.0 mm) in leads without Q waves because of previous MI (other than aVR, aVL, or V ₁)
Drop in systolic BP of >10 mm Hg, despite an increase in workload, when accompanied by any other evidence of ischemia
Moderate to severe angina
Central nervous system symptoms (e.g., ataxia, dizziness, or near-syncope)
Signs of poor perfusion (cyanosis or pallor)
Sustained ventricular tachycardia or other arrhythmia that interferes with normal maintenance of cardiac output during exercise
Technical difficulties monitoring the ECG or systolic BP
Patient's request to stop
Relative Indications
Marked ST displacement (>2 mm horizontal or downsloping) in a patient with suspected ischemia
Drop in systolic BP of >10 mm Hg (persistently below baseline), despite an increase in workload, in the absence of other evidence of ischemia
Increasing chest pain
Fatigue, shortness of breath, wheezing, leg cramps, or claudication
Arrhythmias other than sustained ventricular tachycardia, including multifocal ectopy, ventricular triplets, supraventricular tachycardia, atrioventricular heart block, or bradyarrhythmias
Exaggerated hypertensive response (systolic BP >250 mm Hg and/or diastolic BP >115 mm Hg)
Development of a BBB that cannot be distinguished from ventricular tachycardia

BBB = bundle branch block; BP = blood pressure; MI = myocardial infarction.

TABLE 13-5 Patient Monitoring During Exercise Testing

During the Exercise Period
12-lead ECG during the last minute of each stage or at least every 3 min
Blood pressure during the last minute of each stage or at least every 3 min
Symptom rating scales as appropriate for the test indication and laboratory protocol
During the Recovery Period
Monitoring for a minimum of 6 min after exercise in a sitting or supine position or until near-baseline heart rate, blood pressure, ECG, and symptom measures are reached. A period of active cool down may be included in the recovery period, particularly following high levels of exercise, to minimize the postexercise hypotensive effects of venous pooling in the lower extremities
12-lead ECG every minute
Heart rate and blood pressure immediately after exercise and then every 1 or 2 min thereafter until near-baseline measures are reached
Symptomatic ratings every minute as long as they persist after exercise.
Patients should be observed until all symptoms have resolved or returned to baseline levels

designed to continue until the patient demonstrates signs and/or symptoms necessitating termination of exercise (see [Table 13-4](#)). Whatever modality or protocol is used, standard patient monitoring and measurements are made during and early after exercise, as outlined in [Table 13-5](#).

Treadmill. Treadmill testing provides a more common form of physiologic stress (i.e., walking) in which subjects are more likely to attain a higher oxygen uptake and peak heart rate than during stationary cycling. Cycling may be preferable when orthopedic or other specific patient characteristics limit treadmill testing or during exercise echocardiographic testing to facilitate acquisition of images at peak

exercise. The most frequently used stepped treadmill protocols are the Bruce (Table 13-6), the modified Bruce (Table 13-6), and the Naughton protocols.²

During treadmill exercise patients should be encouraged to walk freely and use the handrails for balance only when necessary. Excessive handrail gripping and support alter the blood pressure response and decrease the oxygen requirement (METs) per given workload, thereby resulting in an overestimation of exercise capacity and an inaccurate heart rate– and blood pressure–to-workload relationship. Exercise capacity (peak METs) can be reasonably estimated for treadmill exercise by using common equations provided by the ACSM,² as long as the equipment is calibrated regularly. When precise determination of oxygen uptake is necessary, such as assessment of patients for heart transplantation (see Chapter 28), evaluation by expired gas analysis is preferred over estimation (see the section [Cardiopulmonary Exercise Testing](#)). Normal values for exercise capacity in healthy adults at different ages are available and may serve as a useful reference in the evaluation of a patient's exercise capacity.⁶

Stationary Cycle. A cycle ergometer is smaller, quieter, and less expensive than a treadmill. Because a cycle ergometer requires less movement of the arms and thorax, quality electrocardiographic recordings and blood pressure measurements are easier to obtain. However, stationary cycling may be unfamiliar to many patients, and its success as a testing tool is highly dependent on patient skill and motivation. Thus the test may end before the patient reaches a true cardiopulmonary endpoint. Unlike treadmill testing, in which the work being performed involves movement of the patient's body weight at a given pace, stationary cycle work involves cycling at a given pace against an external force and is generally independent of the patient's body weight, which is supported by the seat. As shown in Table 13-7, the MET level attained at a given work rate varies with the patient's body weight. Accordingly, at the same given cycle ergometer work rate, a lighter person will attain higher METs than will a heavier person. Mechanically braked ergometers require that the patient's cycling speed be kept constant. Electronically braked cycle ergometers

automatically adjust external resistance to the cycling speed to maintain a constant work rate at a given stage. Electronically braked cycle ergometers allow simple programming of ramp protocols. As with treadmill ramp protocols, customized cycle ergometer ramp protocols that accommodate a wide range of fitness levels need to be established by individual exercise testing laboratories.

Arm Cycle Ergometry. Arm ergometry is an alternative method of exercise testing for patients who cannot perform leg exercise. Although this test has diagnostic usefulness, it has been largely replaced by non-exercise pharmacologic stress techniques.

Six-Minute Walk Test. The 6-minute walk test can be used as a surrogate measure of exercise capacity when standard treadmill or cycle testing is not available. Distance walked is the primary outcome of the test. It is not useful in the objective determination of myocardial ischemia and is best used in a serial manner to evaluate changes in exercise capacity and the response to interventions that may affect exercise capacity over time. The 6-minute walk test protocol is discussed in detail elsewhere⁷ and is provided in Table 13-8.

Cardiopulmonary Exercise Testing. Because of the inaccuracies associated with estimating oxygen uptake ($\dot{V}O_2$) and METs from work rate with the treadmill or cycle ergometer, many laboratories perform cardiopulmonary exercise testing (CPX), which uses ventilatory gas exchange analysis during exercise to provide a more reliable and reproducible measure of $\dot{V}O_2$. Peak $\dot{V}O_2$ is the most accurate measure of exercise capacity and is a useful reflection of overall cardiopulmonary health. Measurement of expired gases is not necessary for all clinical exercise testing, but the additional information can provide important physiologic data that can be useful in both clinical and research applications. Measures of gas exchange primarily include $\dot{V}O_2$, carbon dioxide output ($\dot{V}CO_2$), and minute ventilation. Use of these variables in graphic form provides further information on the ventilatory threshold and ventilatory efficiency. These latter concepts are explored in detail elsewhere.⁶

CPX is useful in the following situations, although applications for CPX continue to broaden:

- Evaluation of exercise capacity in selected patients with heart failure to assist in estimation of prognosis, evaluate the response to medications and other interventions, and assess the need for cardiac transplantation.
- Evaluation of exertional dyspnea. Such testing can provide useful information for differentiating cardiac from pulmonary limitations as a cause of exercise-induced dyspnea or impaired exercise capacity when the cause is uncertain.
- Evaluation of the patient's response to specific therapeutic interventions in which improvement in exercise tolerance is an important goal or endpoint.

The technique of CPX has become simplified with contemporary systems, but meticulous maintenance and calibration of these systems are required for optimal use. The personnel involved in administering and interpreting the test must be trained and proficient in this technique. Finally, the test requires additional time, as well as patient cooperation.⁶

Exercise Test Supervision

Over the past 30 years since the American Heart Association (AHA) published its first set of *Standards for Adult Exercise Testing Laboratories*, the role of the physician in ensuring that the exercise laboratory is properly equipped and appropriately staffed with qualified personnel who adhere to a written set of policies and procedures

TABLE 13-6 Bruce Protocol for Treadmill Testing

STAGE	TIME	SPEED (mph)	GRADE (%)	METs
Rest	00:00	0.0	0.0	1.0
1	03:00	1.7	10.0	4.6
2	03:00	2.5	12.0	7.0
3	03:00	3.4	14.0	10.1
4	03:00	4.2	16.0	12.9
5	03:00	5.0	18.0	15.1
6	03:00	5.5	20.0	16.9
7	03:00	6.8	22.0	19.2

The modified Bruce protocol uses two initial low-level 3-minutes stages at a speed of 1.7 mph and grades 0% and 5%, respectively, and then continues into the full Bruce protocol.

TABLE 13-8 Six-Minute Walk Test Protocol

<p>Testing Site</p> <ul style="list-style-type: none"> • The 6-min walk test protocol should be performed indoors along a long, flat, straight, enclosed corridor with a hard surface that is seldom traveled. The walking course must be 30 meters in length. • A 100-ft (30.4-meter) hallway is required, and its length should be marked every 3 meters. • The turnaround points should be marked with a cone (such as an orange traffic cone). • A starting line, which marks the beginning and end of each 60-meter lap, should be marked on the floor with brightly colored tape.
<p>Measurements</p> <ul style="list-style-type: none"> • Assemble all necessary equipment (lap counter, timer, clipboard, worksheet) and move to the starting point. • Set the lap counter to zero and the timer to 6 min. Position the patient at the starting line. • You should also stand near the starting line during the test. • Do not walk with the patient. • As soon as the patient starts to walk, start the timer. • Do not talk to anyone during the walk. • Use an even tone of voice when using the standard phrases of encouragement. • Each time that the patient returns to the starting line, click the lap counter once (or mark the lap on the worksheet). • At the end of 6 min, tell the patient to stop walking and measure the total distance traveled (meters).
<p>Patient Instructions</p> <p>Standardized scripted patient instructions should be used and are provided elsewhere</p>

Data from American Thoracic Society: ATS statement: Guidelines for the six-minute walk test. *Am J Respir Crit Care Med* 166:111, 2002. Official journal of the American Thoracic Society.

specific to that laboratory has not changed. In subsequent iterations of their respective guidelines, the AHA, the ACSM, the American College of Cardiology (ACC), and the American Association of Cardiovascular and Pulmonary Rehabilitation (AACVPR) have consistently addressed this issue. In the year 2000, the ACC/AHA/American College of Physicians/American College of Sports Medicine Competency Task Force focused its efforts on outlining the specific cognitive and training requirements for personnel involved in supervising and interpreting exercise ECGs and was the first to look beyond the specific professional type (e.g., physician, nurse, exercise physiologist) and focus on specific competencies of the individual staff member.⁸ This statement clearly defined different levels of supervision as follows: (1) “personal supervision” requires a physician’s presence in the room; (2) “direct supervision” requires a physician to be in the immediate vicinity, on the premises or the floor, and be available for emergencies; and (3) “general supervision” requires the physician to be available by phone or by page.⁸ Common to every guideline is the recommendation that patients be screened before exercise testing to assess their risk for an exercise-related adverse event so that the most appropriate personnel to supervise the test can be provided. Exercise testing may be supervised by nonphysician staff members who are deemed competent according to the criteria outlined in the ACC/AHA statement.⁸ In all such cases the physician should be immediately available to assist as needed (i.e., provide direct supervision); in high-risk patients the physician should personally supervise the test (i.e., provide personal supervision).

Risks of Exercise Testing

Exercise is associated with increased risk for an adverse cardiovascular event, and hence details regarding the safety of exercise testing and emergency preparedness in exercise laboratories are addressed in depth in guidelines from the AHA^{1,3} and the ACSM.² Nonetheless, the safety of exercise testing is well documented and the overall risk for adverse events is quite low. In several large series of subjects with

and without known CVD, the rate of major complications (including myocardial infarction and other events requiring hospitalization) was less than 1 to as high as 5 per 10,000 tests, and the rate of death was less than 0.5 per 10,000 tests. The incidence of adverse events depends on the study population.⁶ Patients with recent myocardial infarction, reduced left ventricular systolic function, exertion-induced myocardial ischemia, and serious ventricular arrhythmias are at highest risk.¹ In more than 2000 subjects with New York Heart Association Functional class II to IV systolic heart failure who completed exercise testing in the HF-ACTION (Heart Failure: A Controlled Trial Investigating Outcomes of exercise training) study, there were no deaths and the rate of nonfatal major cardiovascular events was lower than 0.5 per 1000 tests.⁹ A recent report of 5060 CPX studies performed in patients with severe functional impairment and a variety of high-risk cardiac diseases, including heart failure, hypertrophic cardiomyopathy (HCM), pulmonary hypertension, and aortic stenosis, further supports the safety of exercise testing. The adverse event rate was 0.16%, and the most common adverse event was sustained ventricular tachycardia. No fatal events were reported.¹⁰

Maintenance of appropriate emergency equipment, establishment of an emergency plan, and regular practice in carrying out the plan are fundamental to ensuring safety in an exercise testing laboratory.³

EXERCISE TESTING IN PATIENTS WITH CORONARY ARTERY DISEASE

Clinical Responses

Any chest pain produced during the exercise test needs to be factored into the exercise test conclusion and report.

First, are the symptoms reported during the test the same or similar to the reported historical symptoms that prompted the exercise test? If the answer is yes, the clinician can assess the objective test responses and discern whether they support the presence of CAD. If the answer is no, differences between the produced and historical symptoms need to be clarified. In addition, the symptoms produced need to be categorized according to whether they are consistent with angina. Distinguishing anginal from nonanginal chest pain is important at the time of occurrence of the chest pain. Angina is not well localized, pleuritic, or associated with palpable tenderness (see Chapter 11), and the only opportunity to define these qualities may be after the exercise test.

Second, exercise-induced angina is an important clinical predictor of the presence and severity of CAD, equal to or greater than ST-segment depression. Consideration of limiting versus nonlimiting chest pain, in addition to any induced angina, has been incorporated into the Duke treadmill score, as well as into other treadmill scores (see later). These factors will have an impact on prognostic and diagnostic assessment of the test results and ultimately the next step in the clinical evaluation.

Exercise Capacity

Exercise capacity is a strong predictor of mortality and nonfatal cardiovascular outcomes in both men and women with and without CAD.^{11,12} Even though exercise capacity is most accurately measured by CPX, a reasonable estimate can be obtained from treadmill testing alone.¹³ The best methods for estimating predicted METs are the following simple regression equations:

$$\text{Men: Predicted METs} = 18 - (0.15 \times \text{Age})$$

$$\text{Women: Predicted METs} = 14.7 - (0.13 \times \text{Age})$$

The reported exercise time can be translated into metabolic equivalents or METs based on the exercise test protocol. The reported METs can then be expressed as a percentage of the predicted METs. An alternative qualitative classification of functional capacity that adjusts for age and sex is provided in Table 13-9.

In addition to clinical factors, exercise capacity can be related to familiarity with the exercise equipment, level of training, and

TABLE 13-9 Estimated Functional Capacity Relative to Age and Sex

ESTIMATED FUNCTIONAL CAPACITY (METs)					
AGE (yr)	Poor	Fair	Average	Good	High
Women					
≤29	<7.5	8-10	10-13	13-16	>16
30-39	<7	7-9	9-11	11-15	>15
40-49	<6	6-8	8-10	10-14	>14
50-59	<5	5-7	7-9	9-13	>13
≥60	<4.5	4.5-6	6-8	8-11.5	>11.5
Men					
≤29	<8	8-11	11-14	14-17	>17
30-39	<7.5	7.5-10	10-12.5	12.5-16	>16
40-49	<7	7-8.5	8.5-11.5	11.5-15	>15
50-59	<6	6-8	8-11	11-14	>14
≥60	<5.5	5.5-7	7-9.5	9.5-13	>13

1 MET = 3.5 mL/kg/min of oxygen consumption.

From Snader CE, Marwick TH, Pashkow FJ, et al: Importance of estimated functional capacity as a predictor of all-cause mortality among patients referred for exercise thallium single-photon emission computed tomography: Report of 3,400 patients from a single center. *J Am Coll Cardiol* 30:641, 1997.

environmental conditions in the exercise laboratory. Patients who cannot perform an exercise test or who undergo a pharmacologic stress test have a worse prognosis than do those who can perform an exercise test.

Exercise capacity should always be incorporated into the results, conclusions, and/or recommendations of the exercise test report. Exercise capacity can be incorporated into available multivariable scores such as the Duke treadmill score or the method of Lauer (see later and Fig. 13-2) to classify the prognosis as low, intermediate, or high risk.

Hemodynamic Responses

Heart Rate

Maximum Heart Rate

The maximum heart rate with exercise is a fundamental physiologic parameter that provides the clinician relevant information concerning the intensity of exercise, the adequacy of the exercise test, the effect of medications that influence heart rate, the potential contribution to exercise intolerance, and the patient's prognosis.¹⁴ The maximum achievable heart rate (HRmax) is unique for each patient but can be estimated by using regression equations that adjust for the patient's age. The most familiar equation, which was developed principally in middle-aged men, is

$$\text{HRmax} = 220 - \text{Age}$$

Although easy to apply and calculate, there is considerable variability with this equation, especially in patients with CAD who are taking beta blockers. Newer equations¹⁴ have been proposed to replace the 220 – age rule to generate the age-predicted maximum heart rate:

$$\text{Men: HRmax} = 208 - (0.7 \times \text{Age})$$

$$\text{Women: HRmax} = 206 - (0.88 \times \text{Age})$$

$$\text{CAD with beta blockers: HRmax} = 164 - (0.7 \times \text{Age})$$

Chronotropic Incompetence

Inability of the heart to increase its rate to meet the demand placed on it is termed chronotropic incompetence. It is considered an independent predictor of cardiac or all-cause mortality,

POINTS

Age, yr

TOTAL POINTS

3-year survival probability

5-year survival probability

FIGURE 13-2 Cleveland Clinic score: nomogram of multivariable proportional hazards prediction model of total mortality derived from 33,268 patients and validated in 5821 subjects. To determine risk, draw a vertical line from each risk marker to the top line, labeled "POINTS," to calculate the points for each risk marker. The sum of all the points is then marked on the line labeled "TOTAL POINTS." Drop vertical lines from there to yield the 3- and 5-year survival probabilities. For binary variables, 1 means "yes" and 0 means "no." (From Lauer MS, Pothier CE, Magid DJ, et al: An externally validated model for predicting long-term survival after exercise treadmill testing in patients with suspected coronary artery disease and a normal electrocardiogram. *Ann Intern Med* 147:821, 2007.)

as well as other adverse cardiovascular outcomes.¹⁴ This independence also includes the well-established Duke treadmill score.¹⁵

A *submaximal* study is assigned when the peak heart rate achieved is below the age-predicted maximum heart rate. An *inadequate* study is defined by failure to achieve a predefined goal, such as 85% of the age-predicted maximum heart rate. If a patient without known CAD has an inadequate study, the term *nondiagnostic* study is often applied. As with all things, this “nondiagnostic” status is relative. In the presence of any other diagnostic endpoints, such as 2-mm or greater ST-segment depression or exercise-induced hypotension, the heart rate adequacy question becomes irrelevant. One might even extend that argument to reproduction of the patient’s reported chest pain symptoms.

Chronotropic incompetence most commonly has been defined by the adjusted heart rate reserve, which incorporates both resting and peak heart rates, as well as the age-adjusted maximum heart rate. However, before the term chronotropic incompetence is applied, consideration should be given to the effort exerted in performing exercise, present medications, and the reason for termination of the exercise test. Effort applied to the exercise is often defined by the symptoms produced or by indices of perceived exertion such as the Borg scale.¹ These work well in most settings but can also be defined quantitatively by using CPX parameters such as the respiratory exchange ratio. For the usual non-CPX application, the following formula^{14,14a} defines the chronotropic index:

$$\frac{[(\text{HR}_{\text{max}} - \text{HR}_{\text{rest}}) \times 100]}{[(220 - \text{Age}) - \text{HR}_{\text{rest}}]}$$

Failure to achieve a chronotropic index higher than 80% defines the presence of chronotropic incompetence. In patients taking non-trivial doses of beta blockers who are compliant with their medication, a value lower than 62% is considered chronotropic incompetence, but this criterion is not universally accepted.¹⁶ Criteria for assessing chronotropic incompetence in patients with atrial fibrillation have not been established.

Early Heart Rate Acceleration. In addition to deconditioning, early heart rate acceleration can be seen during exercise in patients with atrial fibrillation, hypovolemia, anemia, and left ventricular dysfunction. It has been investigated as a means of assessing autonomic response and prognosis in patients who cannot perform strenuous exercise. Two studies have addressed this topic, one using cycle ergometry and the other using treadmill exercise. Unfortunately, the two studies arrived at opposite conclusions. The treadmill study did find that early heart rate acceleration during the first minute of exercise had a relationship to survival but did not add any further incremental prognostic value to the Duke treadmill score. Therefore this parameter should not be considered in the evaluation of exercise test results until further investigation defines its value and role.¹⁷

Heart Rate Recovery. The heart rate increases during exercise because of an increase in sympathetic tone and a decrease in parasympathetic tone. At the cessation of exercise, under normal circumstances the reverse process occurs. In athletes and normal subjects there is a biexponential response, with an initial steep 30-second fall in heart rate followed by a more shallow decline thereafter. This biexponential response disappears with the administration of atropine and becomes similar to the response in patients with heart failure. Abnormal heart rate recovery (HRR) has been defined by many methods, but the most commonly accepted include less than 12 beats/min after 1 minute with postexercise cool down, less than 18 beats/min after 1 minute with immediate cessation of movement into either the supine or sitting position, and less than 42 beats/min after 2 minutes. In healthy subjects, short-term reproducibility has been demonstrated.¹⁴

Abnormal HRR is associated with an increase in all-cause mortality in both asymptomatic individuals and patients with established heart disease. This association is independent of the chronotropic index, beta blockade, CAD severity, left ventricular function, Duke treadmill score, and ST-segment depression. HRR adds to the prognostic ability of peak Vo_2 . From a mechanistic standpoint, abnormal HRR has been associated with a high prevalence of abnormal and high-risk myocardial perfusion imaging.

Most of the literature focuses on the early phase of HRR, but later HRR, expressed as a percentage of change in cycle length, may be independently predictive of adverse cardiovascular outcomes.¹⁸ This aspect requires further investigation.

Blood Pressure. Exercise blood pressure responses, like those for heart rate, reflect the balance between sympathetic and parasympathetic influences. Systolic blood pressure, pulse pressure (difference between systolic and diastolic pressure), heart rate–blood pressure product (also called the double product), and double-product reserve (change in double product from peak to rest) all increase steadily as workload increases. Diastolic blood pressure increases only minimally. In most normal subjects, systolic blood pressure will increase to higher than 140 mm Hg and the double product to higher than 20,000.¹⁹

Exaggerated Systolic Pressure Response. This response is usually defined as greater than 210 mm Hg in men and greater than 190 mm Hg in women. Even though these exercise responses are considered abnormal, they are not generally reasons to terminate exercise. Such responses may be indicative of the future development of hypertension or adverse cardiac events.²⁰

Exercise-Induced Hypotension. This has been variably defined but is most frequently defined as systolic pressure during exercise falling below resting systolic pressure. Another definition is a 20 mm Hg fall after an initial rise. Either of these definitions would be an absolute reason to terminate the exercise test. The former definition is more predictive of a poor prognosis and is usually related to severe multivessel CAD with left ventricular dysfunction, especially when noted with other signs of ischemia such as ST depression or angina at a low workload. Its positive predictive value is high in men but much lower in women. Its presence usually warrants consideration of prompt invasive evaluation. Exercise-associated hypotension may also be seen in patients with cardiomyopathy, left ventricular outflow tract obstruction, enhanced vagal tone, hypovolemia, antihypertensive medications, and arrhythmias.

One systolic blood pressure response that needs to be appreciated might be called “pseudo-exercise-induced hypotension.” This response occurs in patients who are anxious about the exercise study and begin exercise with a somewhat elevated systolic pressure. As exercise proceeds in the first stage, this elevated pressure usually settles down or “falls” toward its customary resting level. As exercise continues, continued observation reveals a gradual upward trend in blood pressure. Considerable clinical judgment needs to be used when interpreting this response.

Low Systolic Pressure Peak. This is defined as a rise to less than 140 mm Hg or a lower than 10 mm Hg rise overall. After excluding poor exercise effort, this response is often associated with severe CAD and worse cardiovascular outcomes in persons with and without known CAD and warrants further evaluation.

Recovery Systolic Pressure Response. This response has been defined in various ways. It is usually expressed as the ratio of 1-, 2-, or 3-minute recovery pressure to peak exercise pressure. Even though a standard and optimal definition has not been established, most studies have shown a worse cardiovascular prognosis when an abnormal recovery pressure (e.g., peak-recovery ratio of ≥ 0.9) is present. Standardization and further study to determine its independent and incremental predictive prognostic power need to be undertaken.

Double-Product Reserve. This is the difference between the peak and resting double product and is inversely related to cardiovascular events in patients with and without known CAD. It may have greater prognostic power than the maximum heart rate, exercise capacity, and HRR. Values lower than 10,000 warrant further evaluation.

Electrocardiographic Responses

ST-Segment Changes

For decades the change in ST segments (**Fig. 13-3**) was the principal factor considered in the analysis of exercise ECG results. However, the diagnostic value of ST-segment depression has been recognized to be mediocre by current noninvasive test standards, with a sensitivity and specificity of 60% to 70% and 70% to 80%, respectively, based on coronary angiography. When adjusted for referral or workup bias, its sensitivity is lower (45% to 50%) and specificity higher (85% to 90%).²¹ Accordingly, the prognostic value of ST-segment changes has been appropriately placed behind the prognostic value of non-ST-segment variables such as exercise capacity and heart rate responses. Despite these issues, it is still appropriate to consider ST-segment changes, but only in the context of other clinical and non-ST-segment data.

ST-Segment Depression

When considering ST-segment depression it is important to use standards that allow application of uniform criteria. The usual criterion applied to raw data is 1 mm or greater or 0.1 mV or greater of horizontal or downsloping (i.e., <0.5 mV/sec) ST-segment depression in three consecutive beats. This assumes that the PQ point (not the TP segment) is used as the isoelectric reference line and that the point of ST-segment measurement is 60 to 80 milliseconds after the J point. The 60-millisecond post-J point criterion is used at heart rates higher than 130 beats/min. This criterion should be added to and not included with already existing resting ST-segment depression. ST-segment changes in the presence of early repolarization should be measured from the isoelectric line and not the baseline ST elevation. Unlike ST-segment elevation, exercise-induced ST-segment

FIGURE 13-3 Eight typical exercise electrocardiographic patterns at rest and at peak exertion. The computer-processed, incrementally averaged beat corresponds with the raw data taken at the same time point during exercise and is illustrated in the last column. The patterns represent worsening electrocardiographic responses during exercise. In the column of computer-averaged beats, ST80 displacement (top number) indicates the magnitude of ST-segment displacement 80 milliseconds after the J point relative to the PQ junction or E point. ST-segment slope measurement (bottom number) indicates the ST-segment slope at a fixed time point after the J point to the ST80 measurement. At least three non-computer-processed average complexes with a stable baseline should meet the criteria for abnormality before the exercise electrocardiographic result can be considered abnormal. *Normal and rapidly upsloping ST-segment* responses typically occur with exercise. J point depression with rapidly upsloping ST segments is a common response in an older, apparently healthy person. *Minor ST-segment depression* can occasionally occur at submaximal workloads in patients with CAD; in this figure, the ST segment is depressed 0.09 mV (0.9 mm) 80 milliseconds after the J point. A *slow upsloping ST-segment pattern* may suggest an ischemic response in patients with known CAD or in those with a high pretest clinical risk for CAD. Criteria for slow upsloping ST-segment depression include J point and ST80 depression of 0.15 mV or greater and an ST-segment slope greater than 1.0 mV/sec. This pattern may also precede the horizontal or downsloping ST-segment depression that will occur during recovery. *Classic criteria for myocardial ischemia* include horizontal ST-segment depression observed when both the J point and ST80 depression are 0.1 mV or greater and the ST-segment slope is within the range of 1.0 mV/sec. Downsloping ST-segment depression occurs when the J point and ST80 depression are 0.1 mV and the ST segment slope is -1.0 mV/sec. *ST-segment elevation in a non-Q-wave noninfarct lead* occurs when the J point and ST60 are 1.0 mV or higher and represents a severe ischemic response. *ST-segment elevation in an infarct territory (Q wave lead)* indicates a severe wall motion abnormality and, in most cases, is not considered an ischemic response. (From Chaitman BR: Exercise electrocardiographic stress testing. In Beller GA [ed]: Chronic Ischemic Heart Disease. In Braunwald E [series ed]: Atlas of Heart Diseases. Vol 5. Chronic Ischemic Heart Disease. Philadelphia, Current Medicine, 1995, pp 2.1-2.30.)

depression does not localize ischemia to a precise region or vascular bed. The lateral precordial leads are the best for defining positive responses. However, the inferior leads can be helpful in assessing the extent of ischemia when the lateral leads are abnormal as well. Isolated inferior ST depression is frequently falsely abnormal because of the influence of atrial repolarization in these leads.

Although raw data should always be examined, the use of signal-averaged data can be useful, especially when moderate baseline wandering or motion artifact is present. Particular care must be taken to avoid signal averaging that incorporates gross distortions as a result of motion and transient ventricular aberrations such as premature ventricular contractions and intraventricular conduction defects.

Postexercise recovery responses are also important to assess. Occasionally, positive responses are limited to the recovery period, and these have equal significance as changes that occur at peak exercise. The diagnostic and prognostic impression of a positive ST-segment response is enhanced by a longer duration of the changes into recovery. This is also true of the maximum amount of ST-segment depression and the total number of leads reflecting abnormality.

Upsloping ST-Segment Depression

Rapidly upsloping ST depression that resolves quickly is rarely a true-positive response. However, ST-segment depression that is slowly upsloping (0.5 to 1.0 mV/sec) may be considered abnormal, especially if it occurs at low workloads. Its presence during exercise may presage horizontal or downsloping depression in recovery. Heart rate adjustment can be applied to upsloping ST segments (see later).

Lead aVR

An emerging literature suggests that 1-mm or greater ST-segment elevation in lead aVR may be a significant predictor of left main disease, proximal left anterior descending (LAD) disease, or at least multivessel CAD.²² As an isolated marker it appears to be sensitive and has moderate specificity and a high negative predictive value. What is yet unclear is where it fits into the multivariate approach for assessing prognosis.

ST-Segment Adjustments

Heart rate adjustments of ST segments have been proposed as an alternative way to analyze ST-segment depression.²¹ However,

comparative studies have not shown an increase in accuracy. Nevertheless, they can be helpful for borderline cases in which ST depression is upslowing or barely abnormal with traditional criteria and other clinical or exercise data suggest a false-positive result (e.g., low pretest probability or very high heart rate or workload achieved during exercise). Heart rate adjustment can be accomplished via two methods—one complicated and the other simple. The complicated method, known as ST/heart rate slope, is automated and available on most stress testing machines as an option to be toggled on or off. It plots ST depression as a function of heart rate at numerous points during exercise and generates the terminal ST/heart rate slope for each lead. The criterion for abnormality is 2.4 $\mu\text{V}/\text{beat}/\text{min}$. Depending on the protocol used and the duration of exercise, the ST/heart rate slope will not always be calculated because of insufficient data points. The developers of the method proposed a modification of the standard Bruce protocol to increase the points available for analysis. The slightly less intensive Cornell protocol uses 2-minute rather than 3-minute stages and is useful in patients who are not anticipated to exercise beyond stage 2 of the Bruce protocol. The simple method, known as ST/heart rate index, can easily be calculated by dividing the maximum ST-segment depression in microvolts by the difference in resting and peak heart rate. The criterion for abnormality is 1.6 $\mu\text{V}/\text{beat}/\text{min}$.

R wave adjustments have been proposed as a means of adjusting ST-segment depression when R wave height is reduced.²³ The “lead strength” method is accomplished by simply dividing ST-segment depression (in microvolts) by R wave height (microvolts) in lead V_5 or V_6 . The criterion for abnormality is 0.1 or greater for R waves less than 10 μV . Studies to date have suggested significantly improved sensitivity with a slight decrease in specificity.²⁴ However, these adjustments have not been evaluated in a broad spectrum of patients, and further study should be undertaken.

ST-Segment Elevation

The usual criterion applied to raw data is 1 mm or greater or 0.1 mV of ST-segment elevation above the PQ point at 60 milliseconds after the J point in three consecutive beats. The J point may or may not be elevated as well. Without pathologic Q waves, exercise-induced ST elevation usually indicates either significant proximal coronary stenosis or epicardial coronary spasm. In either case the ST-segment elevation precisely localizes the transmural ischemia to a particular vascular region (e.g., anterior = LAD, and hence coronary angiography is an appropriate next step). In contrast, when pathologic Q waves are present, ST-segment elevation is usually indicative of a left ventricular aneurysm or significant wall motion changes. Ischemia may be involved in this process, and myocardial perfusion imaging is generally required to determine this.

QRS Changes

Changes in R Wave Amplitude

Precordial R waves normally increase during exercise. They peak before achieving maximal exercise and decrease as maximal exercise is achieved. If exercise is limited to a submaximal level by any cause, the R waves will appear to increase in height at peak exercise. This increase in R wave height has not been found to have predictive power.

Changes in QRS Duration

During exercise there is a normal shortening of the QRS, as well as the PR and QT intervals. Exercise-induced bundle branch block (BBB) is rare and occurs at a frequency of 0.5% or less. Exercise-induced left BBB (EI-LBBB) has been reported in two large series.²⁵ One series suggested that when EI-LBBB occurs at heart rates higher than 125, significant CAD is unlikely. The incidence of CAD does increase when it occurs at progressively lower heart rates. The other series suggested an increased association of EI-LBBB with death and major cardiac events. The ST-segment changes before onset of the LBBB are still interpretable, but they become uninterpretable once the LBBB begins. Onset and offset of the LBBB usually occur at different heart rates.

In contrast, exercise-induced right BBB (EI-RBBB) from one recent large Veterans Affairs series correlated with age and was not associated with added incremental risk.²⁶ Limited data are available in women. EI-RBBB does not invalidate interpretation of the ST segment for the inferior (II, III, aVF) and lateral leads (V_5 , V_6). ST-segment changes limited to V_1 to V_4 are nondiagnostic.

T Wave Alternans

Isolated T wave changes or inversions during exercise, including so-called pseudonormalized T wave changes, are generally considered to be nonspecific. However, more specialized detection methods to assess microvolt T wave changes and T wave alternans during exercise have found their way into presently existing guidelines. The 2006 ACC/AHA/European Society of Cardiology (ESC) guidelines for the management of ventricular arrhythmias²⁷ assigned a class IIa indication for T wave alternans to improve the diagnosis and risk stratification of patients with ventricular arrhythmias or those at risk for the development of life-threatening ventricular arrhythmias. This method measures microvolt fluctuation in the amplitude of the T wave that alternates every other beat. It is usually assessed during exercise testing or atrial pacing. To date, studies indicate that it has strong negative predictive value but low positive predictive value. Its strong negative predictive value would suggest that T wave alternans could play a role in deciding who would not benefit from placement of a defibrillator. However, T wave alternans should continue to be studied and included in trials to better define its role.

Arrhythmias

Ventricular ectopic activity is commonly noted in up to 20% of patients during exercise testing. It varies from isolated premature ventricular beats (PVBs) to nonsustained ventricular tachycardia. However, frequent ventricular ectopy occurs during exercise or recovery in only 2% to 3% of patients. Suppression of resting ventricular ectopic activity during exercise is a nonspecific finding that can occur with or without CAD.

In clinical populations referred for testing because of symptoms, ventricular ectopic activity during exercise was predictive of mortality in most studies. In addition, ventricular ectopic beats occurring during exercise or recovery increase the likelihood of future cardiac death,²⁸ especially if the beats have a right (as opposed to left) BBB morphology.²⁹ For asymptomatic populations, the correlation between ventricular arrhythmias and either mortality or ischemia was less clear. A correlation between ventricular arrhythmias and ischemia was noted in studies that considered it. This finding probably reflects a relationship between ventricular arrhythmias and both left ventricular function and coronary anatomy. In the absence of sustained ventricular tachycardia requiring immediate treatment, the impact of ventricular arrhythmias during exercise on prognostic assessment is best considered in a multivariable format, which is considered later in this chapter.

Exercise-induced supraventricular arrhythmias are not predictive of ischemia or any cardiovascular endpoint. However, they may be a marker for the later occurrence of atrial fibrillation or supraventricular tachycardia.

Other Electrocardiographic Considerations

The following factors have been reported to improve the accuracy of the exercise ECG²⁴ but have not been studied in large unselected populations.

P Wave Duration

The duration of the P wave in lead V_5 has been reported to increase sensitivity. A duration of 20 milliseconds or less is considered normal, whereas a value of 30 milliseconds or longer is considered abnormal. From a practical standpoint, it is more realistic to expect that these changes would be easier to appreciate with signal-averaged complexes.

ST-Segment Changes in Premature Ventricular Beats

Comparing the ST segments of PVBs before and during exercise has been reported to increase sensitivity.

T Wave Increase

An increase in T wave height by more than 2.5 mV in leads V_2 to V_4 in patients with exercise-induced chest pain has been noted to be a highly specific finding of ischemia.

Medication Effects

Digoxin. The fact that digitalis can have an adverse effect on ST-segment interpretation is generally common knowledge. The ACC/AHA guidelines for exercise testing²¹ give a class IIb recommendation (i.e., could be considered) for an exercise ECG in the presence of digitalis and minor resting ST-segment changes. The principal issue has been false-positive results and reduced specificity. The absence of ST-segment change at rest does not eliminate the effect occurring during exercise. Sensitivity is not affected by digitalis. Therefore a negative ST-segment response with digitalis is still reliable.

However, this issue arises much less frequently in the current era. Although still used, digitalis has become a secondary drug for both heart rate control for patients in atrial fibrillation and treatment of symptomatic heart failure. Its use for the treatment of other supraventricular arrhythmias is virtually nonexistent. For many if not most patients taking digitalis, stress imaging with or without pharmacologic stress is appropriate for reasons other than the presence of digitalis. For the relatively few patients who are taking digitalis and qualify for a simple exercise ECG, individualized decision making can be undertaken to obviate the need for a general policy statement beyond repeating the exercise ECG with imaging if the ST-segment response is abnormal while taking digitalis.

Beta Blockers. It is clear that beta blockers reduce the rate-pressure product in most patients receiving proper doses. Evidence indicates that the diagnostic sensitivity and negative predictive value of exercise testing are adversely affected.

For those without established CAD who are undergoing a diagnostic-level exercise ECG, beta blockers should ideally be withheld to allow an adequate heart rate response. For those undergoing supplemental stress imaging, the issue is less critical given the availability of conversion to pharmacologic stress if the patient fails to achieve the desired heart rate response.

For those with established CAD, the situation is less clear. For most with CAD, beta blockers are part of their standard medical therapy and have significant effects on both their quality and quantity of life (i.e., their prognosis). Many laboratories routinely have patients discontinue beta blockers before stress testing of all sorts without apparent harm. The principal justification for this seems to be to enhance diagnostic sensitivity (e.g., in the case of myocardial perfusion imaging, to allow a larger defect size). Conversely, many laboratories do not discontinue these medications. Discontinuing beta blockers in patients with CAD creates a clinical state that is unlike their usual day-to-day existence. We are unaware of any reported studies in patients with established CAD indicating that beta blockers adversely affected the ability of exercise testing (with or without imaging) to detect prognostically important myocardial ischemia such that it would have significantly altered their clinical management.³⁰ Hence discontinuation of beta blockers before exercise testing may be left to the discretion of the referring physician.

Diagnostic Value of the Exercise Electrocardiogram for Identification of Coronary Artery Disease

Sensitivity and Specificity

The diagnostic characteristics of stress testing are outlined in [Table 13-10](#). Sensitivity and specificity define how effectively a test discriminates subjects with disease from those without disease. Sensitivity is the percentage of individuals with a disease who have abnormal test results and, in the case of CAD, is influenced by disease severity, effort level, and the use of anti-ischemic drugs. Specificity is the percentage of those without disease who have normal test results, and it may be affected by resting ECG patterns (e.g., left ventricular hypertrophy, ST-T abnormalities, interventricular conduction delay) and drugs such as digoxin. All tests have a range of inversely related sensitivities and specificities such that when sensitivity is the highest, specificity is lowest and vice versa. These can be selected by specifying a discriminant or diagnostic cut point.³¹ The standard exercise test cut point of 0.1 mV (1 mm) of horizontal or downsloping

TABLE 13-10 Diagnostic Characteristics of the Exercise Electrocardiogram

TERM	DEFINITION
True positive (TP)	Abnormal test result in an individual with disease
False positive (FP)	Abnormal test result in an individual without disease
True negative (TN)	Normal test result in an individual without disease
False negative (FN)	Normal test result in an individual with disease
Sensitivity	Percentage of patients with CAD who have an abnormal result = $TP/(TP + FN)$
Specificity	Percentage of patients without CAD who have a normal result = $TN/(TN + FP)$
Predictive value of a positive test	Percentage of patients with an abnormal result who have CAD = $TP/(TP + FP)$
Predictive value of a negative test	Percentage of patients with a normal result who do not have CAD = $TN/(TN + FN)$
Test accuracy	Percentage of true test results = $(TP + TN)/\text{total number of tests performed}$

Modified from Chaitman BR: Exercise stress testing. In Bonow RO, Mann DL, Zipes DP, Libby P (eds): Braunwald's Heart Disease. 9th ed. WB Saunders, Philadelphia, 2012.

ST-segment depression in three consecutive beats of at least a single lead has been selected as the discriminating cut point and has a sensitivity of 68% and specificity of 77%.²¹ Once a discriminant value that determines a test's specificity and sensitivity is chosen, the population tested must be considered. If the population is skewed toward individuals with a greater severity of disease, the test will have higher sensitivity. Thus the exercise test has higher sensitivity in individuals with triple-vessel disease than in those with single-vessel disease.¹ The sensitivity and specificity of stress testing are limited by the use of angiographic CAD as the diagnostic "gold standard," and hence most data are derived from studies in which patients underwent both exercise testing and cardiac catheterization. The data are therefore subject to workup bias, which inflates the estimated sensitivity and deflates the specificity because patients selected for coronary arteriography are more likely to have obstructive CAD,¹ and in some studies patients with a positive test result were more likely to be referred for angiography.

The *diagnostic accuracy* of a test is the percentage of true test results (total true positives plus total true negatives) among all tests performed. Diagnostic accuracy is additionally influenced by the criteria used to determine whether an adequate level of stress has been achieved. This is currently defined as having attained 85% of the maximum predicted heart rate, with the maximum predicted heart rate being estimated from the equation $220 - \text{age}$ (see the section [Heart Rate](#)). Despite many limitations in using this latter equation for diagnostic purposes, it remains a standard criterion for test adequacy but should not be used as a reason to terminate the test.

Positive and Negative Predictive Values

Predictive values (see [Table 13-10](#)) further define the diagnostic value of a test. The predictive value of a test is heavily influenced by the prevalence of disease in the group being tested. Bayes' theorem states that the probability of a person having the disease after the test is performed is the product of the probability of the disease before testing and the probability that the test provided a true result. Thus a test has a higher positive predictive value and lower negative predictive value when used in a population with a high prevalence; conversely, a higher negative predictive value and lower positive predictive value occur in a population with a lower prevalence. For example, an exercise ECG that demonstrates ST depression in an elderly person with typical anginal symptoms is most likely a true-positive result, whereas that in a young asymptomatic person without cardiac risk factors is most likely a false-positive result.

TABLE 13-11 ACC/AHA Practice Guidelines on Exercise Testing: Pretest Probability of Coronary Heart Disease by Age, Sex, and Symptoms

AGE (YEAR)	TYPICAL/DEFINITE ANGINA PECTORIS	ATYPICAL/PROBABLE ANGINA PECTORIS	NONANGINAL CHEST PAIN	ASYMPTOMATIC
30-39	Intermediate	Very low	Very low	Very low
40-49	Intermediate	Low	Very low	Very low
50-59	Intermediate	Intermediate	Low	Very low
60-69	High	Intermediate	Intermediate	Low
≥70	High	Intermediate	Intermediate	Low

Modified from Gibbons RJ, Balady GJ, Bricker JT, et al: ACC/AHA 2002 guideline update for exercise testing: Summary article. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to Update the 1997 Exercise Testing Guidelines). *J Am Coll Cardiol* 40:1531, 2002.

Pretest and Post-Test Probability of Disease

Table 13-11 demonstrates the pretest probability of obstructive CAD based on age, sex, and symptoms. However, these can be refined further with knowledge of the presence and extent of traditional atherosclerotic risk factors (e.g., hypertension, hyperlipidemia, smoking, diabetes).^{32,33} Using exercise ST-segment criteria, the post-test likelihood of obstructive CAD can be estimated for a given individual if an ischemic response was demonstrated at any heart rate or if the patient attained a heart rate of 85% or greater of the predicted maximum without an ischemic response.

Assessment of the Anatomic and Functional Extent of Coronary Artery Disease

As discussed earlier in this chapter (see [Physiology of Exercise Testing](#)), several factors influence the significance of a given coronary artery luminal stenosis, and these factors may affect the presence and extent of myocardial ischemia relative to exercise-induced increases in myocardial oxygen demand. Furthermore, exercise-induced ST-segment depression does not provide a reliable assessment of the extent of disease or the specific coronary vessel or vessels involved. ST-segment elevation in leads without Q waves, although an uncommon response, generally reflects transmural ischemia that can be localized by the leads involved: leads V_2 to V_4 reflect LAD disease; lateral leads reflect left circumflex and diagonal vessel disease; and leads II, III, and AVf reflect right coronary artery disease (in a right-dominant circulation).²¹ Other factors related to the probability and severity of CAD include the degree, time of appearance, duration, and number of leads with ST-segment depression or elevation. It is important to realize, however, that prognostically important CAD may be present in the absence of obstructive lesions. Hence the use of diagnostic ST-segment analysis alone during exercise testing is inadequate and should be done with consideration of several non-ST-segment variables as discussed in the section on prognosis later.³⁴

Exercise Electrocardiographic Testing in Women

Identification of CAD in women can be a diagnostic challenge because of several factors, including the lower prevalence of obstructive CAD in women younger than 65 years, more atypical manifestations of ischemic symptoms, and more frequent resting ST changes. In women with a low pretest likelihood of CAD, exercise electrocardiographic testing results in a minimal change in assessment from pretest levels. Premenopausal women with one or fewer risk factors for CAD and with nonanginal or atypical symptoms will have a high rate of false-positive tests. Hence the exercise ECG in such women is of little value except perhaps in selected cases to reassure women with atypical symptoms regarding their low likelihood of obstructive CAD when they have no exercise-induced ischemic ST changes and a low-risk Duke treadmill score.

The reported sensitivity and specificity of exercise electrocardiographic testing in symptomatic women vary greatly depending on the study characteristics and range from 31% to 71% and 66% to 86%, respectively.³⁵ However, exercise testing has similar diagnostic characteristics in women with an intermediate probability of CAD as it does for men. Thus exercise electrocardiographic testing has the greatest incremental value in intermediate-risk women, particularly when coupled with the Duke treadmill score. In a series of 976 symptomatic women referred for exercise testing and coronary angiography, a low-, intermediate-, and high-risk score was associated with obstructive CAD (>75% luminal narrowing) in 19%, 35%, and 89% of women, respectively. Moreover, 2-year cardiac mortality rates in this same cohort of women with low-, moderate-, and high-risk Duke treadmill scores were 1%, 2%, and 4%, respectively. Non-ST-segment variables, including peak exercise capacity (METs), chronotropic response, HRR, and blood pressure response, have prognostic value in women³⁵ and are most useful when incorporated into the prognostic scores discussed later in this chapter. The usefulness of exercise stress testing in the assessment of women for CAD has been reviewed in detail by the AHA³⁶ and is outlined in [Figure 13-4](#). The exercise ECG remains the recommended test of first choice for the assessment of symptomatic, intermediate-risk women who can exercise and have normal findings on a resting ECG. A negative and diagnostically adequate test, particularly when associated with low risk scores, makes the likelihood of obstructive CAD very low. A positive or inconclusive test generally requires further evaluation with either a stress imaging test or coronary angiography.

Prognostic Value of the Exercise Electrocardiogram

Prognostic Variables

The strongest predictor of prognosis derived from the exercise test is exercise capacity. The weakest predictor is ST-segment depression. All other variables, such as the heart rate achieved, HRR, blood pressure response, ventricular arrhythmias, and exercise-induced angina, fall between these two extremes. This prognostic hierarchy is similar in both men and women.

Prognostic Scores. Multivariable scores are the best way to distill the relative prognostic values of many variables into a single indicator of risk that can be expressed as both continuous (e.g., 0 to 100) and ordinal variables (e.g., low, intermediate, and high). To date, three scores have been developed and validated and are worthy of consideration in analyzing exercise tests.

Duke Treadmill Score. This score¹ has been available since the early 1990s and is the most widely recognized, used, and validated score. It was cited in the 1997 and subsequent updates of the ACC/AHA exercise test guidelines. It incorporates three treadmill variables: exercise time (Bruce protocol), millimeters of any ST-segment deviation (except aVR), and angina score index (1 = nonlimiting angina and 2 = exercise-limiting angina). It is simple enough to present as the equation

$$\text{Score} = \text{Exercise time} - (5 \times \text{ST deviation}) - (4 \times \text{Angina index})$$

ST deviation is the largest net ST-segment displacement in any lead. It is equally valid in men and women, and its prognostic value is independent of clinical, coronary anatomic, and left ventricular function data. The principal criticism of the Duke score is the absence of consideration of clinical variables, especially age or other exercise test variables such as heart rate. Modifications of the score to include

age and double-product reserve have been developed in male populations³⁷ but to date have not been validated in other populations, including women.

Sex-Specific Scores. These scores were developed and validated in the early 2000s.³² Separate scores for men and women incorporate three standard exercise test variables (ST-segment depression, peak heart rate, exercise angina score) and several other clinical variables (Fig. 13-5). These scores are not as simple as the Duke treadmill score but lend themselves to easy clinical application and have been applied to expert systems.

Cleveland Clinic Score. This score was initially reported in 2007.³³ It incorporates most of the important prognostic exercise test variables, as well as other important clinical variables (see Fig. 13-2). The displayed nomogram is more difficult to apply in routine clinical settings, but it is available in a more user-friendly free online software application (<http://rcc.simpal.com/5K0U5R>).

Post-Mycardial Infarction Status

Since 2002, when the last full set of exercise testing guidelines was updated,²¹ treatment of myocardial infarction and evaluation of post-myocardial infarction patients have evolved greatly. In those guidelines, exercise testing carried class I indications before hospital discharge (sub-maximal 4 to 7 days), 14 to 21 days after discharge (symptom limited if not performed before discharge), and 3

B

FIGURE 13-5 Exercise test scores for men (A) and women (B). To determine the risk group, total the points for the appropriate choice for each clinical and exercise test variable. If no choice is appropriate for a particular variable, score points as zero for that variable. ST-segment depression is only horizontal or downsloping. Diabetes is insulin or non-insulin requiring. Smoking is any current or previous cigarette smoking. Estrogen status positive would be women who are premenopausal, are receiving hormone replacement therapy, or have intact ovaries and are younger than 50 years. Otherwise, women are estrogen status negative. (From Raxwal V, Shetter K, Morise A, et al: Simple treadmill score to diagnose coronary disease. *Chest* 119:1933, 2001; Morise AP, Lauer MS, Froelicher VF: Development and validation of a simple exercise test score for use in women with symptoms of suspected coronary artery disease. *Am Heart J* 144:818, 2002.)

to 6 weeks after discharge (symptom limited if predischARGE submaximal performed). These recommendations were based largely on the then existing ACC/AHA guidelines for the management of acute myocardial infarction. In this setting the exercise test was found to be safe, with a reported mortality rate of 0.03% and a nonfatal event rate of 0.09%.

The original 1997 guidelines also assigned two other indications. The first was a class IIb indication to identify ischemia in patients who underwent angiography in which lesions of questionable significance were identified. The follow-up 2002 update of the guidelines²¹ changed this to a class III indication, thus indicating that stress imaging was the preferred strategy for evaluating suspicious coronary anatomy. The second was a class IIa indication as part of an exercise prescription before cardiac rehabilitation for patients who underwent coronary revascularization. On reviewing the most recent guidelines for both ST-elevation myocardial infarction (STEMI)³⁸ and non-STEMI,³⁹ this recommendation continues (see [Chapters 52 and 53](#)).

However, since 1997 the use of coronary angiography as part of the diagnostic evaluation and treatment of myocardial infarction has moved to the front of the line. This evolution has limited the role of exercise testing in the stratification of postinfarction patients. The most recent guidelines for both STEMI³⁸ and non-STEMI³⁹ state that the role of the simple exercise ECG is limited to patients who did not undergo coronary angiography following thrombolytic therapy or to patients who did not receive reperfusion therapy. In addition, these patients should have left ventricular ejection fractions greater than 40% and no other high-risk features, be able to exercise, and have interpretable ECGs. This subset of patients is likely to be a small percentage of the total postinfarction group. In addition, it is highly likely that many of these patients will undergo stress imaging rather than a simple exercise test. Nevertheless, when exercise testing is performed, the variables of prognostic importance are the same as in all other settings, namely, exercise capacity, heart rate, systolic blood pressure, and ventricular arrhythmias.

In the present clinical environment, realistic goals of exercise testing in the post-myocardial infarction setting, whenever it is performed, should be threefold: to provide (1) a functional evaluation to guide the exercise rehabilitation prescription, (2) a basis for advice concerning return to work and other physical activities, and (3) an evaluation of present therapy.

Preoperative Assessment for Noncardiac Surgery

Published guidelines for the preoperative evaluation of patients undergoing noncardiac surgery (see [Chapter 80](#)) indicate a role for exercise testing in this process.⁴⁰ The guidelines outline a five-step process beginning with yes or no questions dealing with emergency status, the presence of active cardiac conditions, and low surgery-specific risk status. If the answer to any of these questions is yes, the process generally leads away from consideration of exercise testing. If the answer to each of these questions is no, the next question in the sequence is functional capacity. The cut point of importance is 4 METs, which can usually be defined by a simple clinical questionnaire. However, if the determination is not well defined by the clinical history, there is a role for a simple exercise electrocardiographic test. If functional capacity is poor, it is likely that most clinicians would use stress imaging given the high likelihood of an inadequate exercise study.

Therapeutic Assessment

The exercise ECG can be applied to assess the efficacy of therapy, whether medication or revascularization. Serial exercise testing can be performed to assess the heart rate and double product at the onset of ischemia (i.e., angina or ST-segment depression). These parameters are generally chosen because of their reproducibility. Peak $\dot{V}O_2$ is the most reproducible measure, but CPX is not performed routinely.²⁵ Exercise time is not generally chosen because of the influence of exercise training on the peripheral musculature with serial testing.

EXERCISE TESTING IN PATIENTS WITH NONATHEROSCLEROTIC HEART DISEASE

The latest iteration of guidelines from the ACC/AHA concerning exercise testing is dominated by diagnostic and prognostic assessments of atherosclerotic CAD.²¹ Less prominent are applications that pertain to certain nonatherosclerotic conditions. In each case, exercise imaging, especially with echocardiography, provides important information for evaluation of these conditions. The following emphasizes and expands on the value of the simple exercise test.²⁸

Valvular Heart Disease

The role of exercise testing in patients with valvular heart disease is best exemplified in the presently available valvular heart disease guidelines from the AHA/ACC, which were updated in 2014 (see [Chapter 63](#)).⁴¹ The role of stress testing was also addressed in 2009 in a review.⁴² Frequently, exercise testing is combined with echocardiography to assess structural and physiologic responses. This is the preferred approach in evaluating patients with mitral stenosis and disparate clinical and resting echocardiographic data, such as severe stenosis without symptoms or symptoms with mild to moderate stenosis. Exercise testing also has a role in patients with valvular heart disease who wish to participate in competitive athletic activity.⁴³ In patients with chronic severe mitral or aortic regurgitation, the diagnostic role of exercise testing is limited to the evaluation of exercise capacity in patients with equivocal symptoms. The only valve lesion in which the simple exercise ECG still has a significant role in management is aortic stenosis.

Aortic Stenosis

It is universally agreed that exercise testing is absolutely contraindicated in patients with symptomatic severe valvular aortic stenosis.^{41,42} However, for asymptomatic patients, exercise testing has found a role in two specific scenarios.

Severe Acquired Aortic Valve Stenosis

The first scenario is asymptomatic patients with severe valvular aortic stenosis, defined as a peak Doppler velocity of 4 meters/sec or greater, valve area less than 1 cm², or a mean valve gradient greater than 40 mm Hg with associated normal left ventricular systolic function.²⁸ Recent data suggest that when peak aortic velocity exceeds 5.5 meters/sec, exercise testing should not be done even in the absence of symptoms.⁴⁴ In addition, patients with severe aortic stenosis and high-gradient and normal left ventricular function are to be distinguished from those with low-flow, low-gradient stenosis and reduced left ventricular function.

Customary practice is to defer aortic valve replacement until symptoms develop (see [Chapter 63](#)). However, some patients with asymptomatic severe aortic stenosis who do not undergo early aortic valve replacement are still at increased short- and longer-term risk. The purpose of exercise testing in this setting is to induce either symptoms or an abnormal blood pressure response (class IIa, level of evidence B). The class IIa indication clearly places it in the “it is reasonable” category. The intent is to provide a basis for a recommendation for valve replacement in patients who do not report any of the expected symptoms of severe aortic stenosis. The safety of exercise testing in this setting is established within the guidelines provided later.

Exercise testing in this scenario should be performed only in those with no reported symptoms or with symptoms that are equivocal at worst such that aortic valve surgery is not indicated on that basis. They should have no extracardiac factors that limit exercise, and they should not have contraindications to aortic valve replacement. Protocols less intense than the standard Bruce protocol should be used, especially in elderly or untrained individuals. A modified Bruce or other low-level protocol can be used for patients who might manifest an earlier than anticipated adverse response. Special emphasis should be placed on the minute-by-minute blood pressure response, patient symptoms, and heart rhythm. Exercise should be terminated

TABLE 13-12 Treadmill Exercise Testing in Patients with Acquired Aortic Stenosis

Appropriate Patients
Asymptomatic or equivocally symptomatic severe valvular aortic stenosis
Mean Doppler aortic valve gradient >40 mm Hg
Peak aortic valve velocity of 4-5.5 meters/sec
Valve area <1 cm ²
Normal left ventricular systolic function
Able to perform treadmill exercise
No contraindications to aortic valve surgery
Treadmill Specifics
Modified Bruce protocol with less intense early stages
Minute-by-minute blood pressure assessment
Cool-down walk without supine recovery
Normal Exercise Response
Predicts absence of stenosis-related symptoms and death for 1 year
Early valve surgery can be delayed
Normal blood pressure response
No decrease from baseline
Exercise-associated increase of >20 mm Hg
Fall of <10 mm Hg from peak
No angina or dizziness
No complex ventricular ectopy
Age-appropriate exercise capacity

Any abnormality would suggest a patient appropriate for early valve surgery.

for limiting dyspnea and fatigue, any angina or dizziness, any decrease in systolic blood pressure, and complex ventricular ectopy. With the exception of limiting dyspnea and fatigue, all of these should be considered abnormal responses placing the patient in a higher risk group. Limiting dyspnea and fatigue have to be interpreted carefully according to what is appropriate for age- and sex-based expectations. If possible, termination should include a 2-minute cool-down walk and avoidance of the supine position to obviate acute left ventricular volume overload. The average follow-up in exercise studies was approximately 1 year, thus suggesting a potential warranty period for favorable exercise test results. See **Table 13-12** for a summary of the usefulness of exercise testing in this scenario.

Moderate to Severe Congenital Valvular Aortic Stenosis

The second scenario consists of young or adolescent patients with congenital aortic stenosis that is moderate to severe, defined as a mean Doppler gradient greater than 30 mm Hg or a peak Doppler gradient greater than 50 mm Hg (class IIa, level of evidence B).^{28,41} Exercise testing in this specific scenario is done to provide advice for patients wishing to participate in athletic activities and to evaluate patients with disparate clinical and Doppler findings regarding the severity of aortic stenosis to determine appropriateness for valve replacement or valvuloplasty. The testing procedure is similar to that for acquired aortic stenosis.

Hypertrophic Cardiomyopathy

In the 2002 ACC/AHA guidelines for exercise testing,²¹ HCM is listed as a relative contraindication (see **Chapter 66**). In the 2011 ACC/AHA guidelines on HCM,⁴⁵ the exercise test carries a class IIa indication for assessing response to therapy (level of evidence C) and for risk stratification (i.e., rhythm and blood pressure [level of evidence B]). Concerning the issue of safety, several reported series have indicated a low and acceptable incidence of fatal and nonfatal complications.

Exercise testing in patients with HCM appears to have clinical value in three clinical situations.²⁸ The first is defining the presence of exercise-induced outflow tract obstruction via Doppler echocardiography in patients with no gradient at rest. The second is identifying patients with coexistent CAD, and the third is detecting patients with the high-risk indicator of an abnormal blood pressure response.

The first two questions require exercise testing with imaging. Exercise testing in symptomatic patients with no significant resting peak outflow tract gradient (i.e., <50 mm Hg) appears to be safe and useful for detecting an exercise-induced gradient (class IIa, level B). A positive

gradient response indicates obstructive rather than nonobstructive HCM. When the presence of significant CAD is being considered, left ventricular hypertrophy and associated ST-segment changes at rest contribute to the reduced specificity of the exercise ST-segment response in this setting. In actual practice, when upright treadmill exercise is performed to address this question, imaging will be used with careful assessment of the blood pressure response.

An abnormal blood pressure response during maximal upright treadmill exercise is a risk factor for sudden cardiac death in patients with HCM (see **Chapter 66**). It is of greater predictive value in patients younger than 50 years. Patterns of an abnormal blood pressure response have been reported: (1) a continuous fall in systolic pressure from the start of exercise, (2) a sudden fall in systolic pressure from the peak value, or (3) a peak systolic increase of less than 24 mm Hg. Patients with abnormal blood pressure responses tend to have more frequent exercise-induced ST-segment depression. The negative predictive value for sudden cardiac death is reported to be in the mid 90% range, whereas the positive predictive value is low. According to the HCM guidelines,⁴⁵ patients are considered low risk if they demonstrate eight characteristics, including a normal exercise blood pressure response. Therefore, although a normal blood pressure response can be reassuring, an abnormal response only places the patient into a high-risk cohort. The implication is that further stratification is required beyond the abnormal blood pressure response.

Adult Congenital Heart Disease

The 2008 ACC/AHA congenital heart disease guidelines⁴⁶ outline the role of the simple exercise test for the evaluation of patients with selected congenital defects (see **Chapter 62**). In each case a specific class recommendation was given. The following recommendations do not include assessment of exercise capacity with CPX or assessment of ischemia with stress imaging.

For patients with outflow tract obstruction, the exercise test has a role with or without consideration of athletic participation (class IIa, level of evidence C). For valvular aortic stenosis, see the previous section on **valvular heart disease**. Similar class IIa recommendations are found for discrete subaortic and supra-aortic stenosis. However, in the latter condition an additional intent is to assess the adequacy of the coronary arteries. In patients with unrepaired coarctation of the aorta, exercise testing should be done to assess for exercise-induced hypertension (peak systolic pressure >230 mm Hg), and the exercise systolic blood pressure response can be used as a surrogate evaluation of the coarctation gradient (class I, level of evidence B). This is in addition to the class IIa recommendation, which is similar to that for valvular aortic stenosis. Finally, in asymptomatic patients with repaired tetralogy of Fallot, periodic (i.e., every 2 to 3 years) exercise testing can be used to assess for high-grade ventricular ectopy (class I, level of evidence C).

The 36th Bethesda Conference^{47,48} addressed the use of simple exercise testing in individuals with congenital heart disease who wish to participate in athletics. This does not include the individualized exercise prescription that could be done on any patient in this scenario. For sport-specific intensity levels, the reader is referred to the document.⁴⁸

For patients with a closed atrial septal defect (surgical or interventional), an exercise test should be performed 3 to 6 months following closure when patients have evidence of pulmonary hypertension, symptomatic atrial or ventricular arrhythmias, second- or third-degree atrioventricular block, or evidence of myocardial dysfunction. After repair or aortic coarctation, patients should be reassessed 3 months later. For patients with repaired transposition of the great vessels or repaired Ebstein anomaly, a normal response to exercise testing plays an important role in providing guidance. Exercise testing plays a critical role in patients with repaired coronary anomalies and residual coronary abnormalities associated with Kawasaki disease, but stress imaging is recommended concomitantly.

Arrhythmias

Indications for exercise testing in the evaluation of arrhythmias are summarized in **Table 13-13**. In the 2002 ACC/AHA exercise test guidelines,²¹ the only scenario in which exercise testing was not recommended (class III) was for the evaluation of young patients with isolated ectopic beats. However, the 36th Bethesda Conference⁴⁹ in 2005 and the ESC consensus on eligibility recommendations for competitive athletes with cardiovascular abnormalities⁴⁷ suggest that exercise testing is appropriate in this setting. The ACC/AHA

TABLE 13-13 Indications for Exercise Testing with Known or Suspected Arrhythmias

CLASS	INDICATION
I	<ol style="list-style-type: none"> 1. Assessment of rate-adaptive pacemakers (heart rate response) 2. Congenital complete heart block in patients considering increased physical activity or competitive sports (heart rate response)
Ila	<ol style="list-style-type: none"> 1. Known or suspected exercise-induced arrhythmias (arrhythmia provocation) 2. Evaluation of medical, surgical, and ablative therapy in patients with exercise-induced arrhythmias (arrhythmia suppression) 3. Evaluation of atrial fibrillation <ol style="list-style-type: none"> a. Suspected myocardial ischemia and before type I-C antiarrhythmic drug therapy (ST depression) b. Assessment of the adequacy of rate control (heart rate response) 4. T-wave alternans for diagnosis and risk stratification (T-wave alternans)
IIb	<ol style="list-style-type: none"> 1. Isolated ventricular ectopic beats in middle-aged patients without evidence of coronary disease (recovery and right bundle branch morphology) 2. Any significant cardiac arrhythmia or electrocardiographic prearrhythmic marker of risk (heart rate response)

Modified from Gibbons RJ, Balady GJ, Bricker JT, et al: ACC/AHA 2002 guideline update for exercise testing: Summary article. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to Update the 1997 Exercise Testing Guidelines). *J Am Coll Cardiol* 40:1531, 2002.

guidelines also make an exception for isolated ventricular ectopic beats in middle-aged patients without other evidence of CAD (class IIb, level of evidence C). Therefore, after careful clinical consideration, there are no absolute class III designations in patients with rhythm disorders.

Class I indications include use with rate-adaptive pacemakers (see later discussion) and use in patients with congenital complete heart block who are considering participation in increased physical activity or competitive sports. The 36th Bethesda Conference in 2005⁴⁹ expanded this indication to any significant cardiac arrhythmia or electrocardiographic prearrhythmic marker of risk in a competitive athlete. These prearrhythmic markers include prolonged first-degree atrioventricular block, type I second-degree Wenckebach atrioventricular block, LBBB, and RBBB (class IIb).

Class IIa indications for exercise testing in patients with heart rhythm disorders include evaluation of those with known or suspected exercise-induced arrhythmias and evaluation of medical, surgical, or ablative therapy in patients with exercise-induced arrhythmias (including atrial fibrillation).

Atrial Fibrillation

The atrial fibrillation guidelines⁵⁰ state that exercise testing should be performed for two specific scenarios (see Chapter 38). The first indication is when myocardial ischemia is suspected and consideration is being given to initiate type IC antiarrhythmic drug therapy. No specific reference was provided implying that this is a general consensus recommendation. In addition, after initiating class IC drugs, exercise testing may help detect QRS widening (should not exceed 50%) that occurs only at rapid heart rates. The second indication was for assessing the adequacy of heart rate control across a full spectrum of activity in patients with persistent or permanent atrial fibrillation. No standard method for assessment of heart rate control has been established to guide management in patients with atrial fibrillation. Criteria for rate control vary with patient age but usually involve achieving ventricular rates between 90 and 115 beats/min during moderate exercise.

Preexcitation

Exercise testing is not considered useful in asymptomatic patients with Wolff-Parkinson-White (WPW) syndrome.⁵¹ A recent report

suggested that loss of preexcitation may be related to the location of the accessory pathway rather than its conduction characteristics.⁵² Presently, it is not recommended that exercise testing be used to stratify asymptomatic patients with the WPW electrocardiographic pattern. Instead, patients should be referred for electrophysiologic evaluation.

Ventricular Arrhythmias

The 2006 ACC/AHA/ESC guidelines for ventricular arrhythmias²⁷ recommend that exercise testing be performed as a class I indication for known or suspected exercise-induced ventricular arrhythmias to provoke and diagnose the arrhythmia and determine response to the tachycardia. Exercise-induced ventricular arrhythmias can be associated with CAD. Therefore detection of ischemia with or without associated ventricular arrhythmias defines a role for the exercise test.

With respect to patients with known or suspected exercise-induced ventricular arrhythmias, it should be understood that exercise testing in this high-risk cohort is not a low-risk endeavor. However, an exercise test may assist in uncovering significant arrhythmias in a controlled clinical environment rather than in the patient's everyday setting.

Catecholaminergic Polymorphic Ventricular Tachycardia

This arrhythmia occurs in genetically predisposed individuals when they are subjected to intense emotional or physical stress.²⁸ Standard cardiac testing at rest usually produces normal results. The arrhythmia is almost always inducible by a maximal exercise test and is frequently not inducible with programmed electrical stimulation. Catecholaminergic polymorphic ventricular tachycardia generally appears above heart rates of 120 to 130 beats/min and begins with ventricular premature beats progressing to nonsustained ventricular tachycardia and eventually to bidirectional or polymorphic ventricular tachycardia. The purpose of the exercise test, therefore, is to achieve a diagnosis and determine the patient's response to treatment, namely, beta blockade.

Long-QT Syndrome

When long-QT syndrome is suspected, exercise testing can be performed safely given that arrhythmias do not usually develop in patients with long-QT syndrome during exercise (see Chapter 32). In addition, changes in the QT interval with exercise can be useful in identifying and stratifying patients with this syndrome.²⁸ Further prolongation of (or failure to shorten) an already prolonged QT interval with exercise is typical of long-QT1 syndrome. Long-QT2 syndrome has normal shortening, whereas long-QT3 syndrome has supranormal shortening of the QT interval with exercise. Beta blockade normalizes these responses. These responses can be useful in predicting and directing genetic testing in patients with long-QT syndrome.

Arrhythmogenic Right Ventricular Cardiomyopathy

Even though arrhythmias and sudden cardiac death can occur during exercise in patients with arrhythmogenic right ventricular cardiomyopathy, exercise testing has no significant role in the management of these patients.

Brugada Syndrome

Exercise testing generally plays little role in the diagnosis of this condition but might have a role in risk-stratifying patients who are asymptomatic. A recent report suggested that augmentation of early precordial ST-segment elevation early in recovery from exercise is both specific to Brugada syndrome and a predictor of a poor prognosis.⁵³ This finding requires further investigation.

Post Therapeutic Assessment

Assessing the response to medical, ablative, or surgical therapy for exercise-induced ventricular arrhythmias is a class IIa, level of evidence B indication.²⁷ Unlike anti-ischemic therapy, the endpoint is the presence or absence of significant ventricular arrhythmias with reasonable levels of exercise, depending on patient-specific factors.

Pacemaker Function

Even though the 2002 guidelines for exercise testing²¹ endorse exercise testing with rate-adaptive pacemakers (class I) to fine-tune or maximize the physiologic response, the 2012 guidelines regarding device-based treatment of cardiac arrhythmias⁵⁴ do not even mention the use of exercise testing with implanted pacemakers. This discrepancy raises a practical question. Despite the original endorsement of exercise testing in patients with rate-adaptive pacemakers, do pacemaker physicians actually use exercise testing in clinical decision making for rate-adaptive pacemakers? Exercise testing could play a role with rate-adaptive pacemakers when exercise intolerance is not completely relieved by factory settings or empiric adjustments. This would be especially true in patients involved in significant physical activities or athletic participation. Protocols to guide the pacemaker physician in selecting the appropriate heart rate ranges for usual physical activity have been proposed, but they require validation.²⁸

ADDITIONAL USES OF EXERCISE TESTING

Chest Pain Units

Chest pain units are designed to assist in the triage and management of low-risk patients among the more than 8 million patients evaluated in emergency departments annually. Low-risk patients have stable hemodynamic signs, no arrhythmias, normal or near-normal findings on the ECG, and negative cardiac injury biomarkers and are appropriate for admission and observation in a chest pain unit. Such units are designed to provide an integrated approach to further risk stratification by short-term observation, repeated ECGs, and serial cardiac injury biomarkers. In patients without further chest pain and no objective evidence of ischemia, an exercise test can be performed after 8 to 12 hours of observation. Such testing is often performed with a symptom-limited treadmill protocol. Several studies encompassing more than 3000 such patients have demonstrated that a negative test (see **Table 13-14**) has a high negative predictive value for subsequent cardiac events. No adverse events during exercise testing have been reported. Those with a positive test are admitted for further evaluation, whereas those with a negative test can be discharged safely with outpatient follow-up. This strategy has been shown to be cost-effective in comparison to usual care in which such patients are admitted to the hospital.⁵⁵ Patients who are unable to exercise or who have baseline electrocardiographic abnormalities can undergo stress imaging tests or computed tomographic

angiography. The usefulness of such tests is discussed in detail elsewhere⁵⁵ (see **Chapters 16 and 18**).

Physical Activity and Exercise Prescription

Data derived from the exercise test can yield valuable objective information to assist in providing physical activity recommendations for patients with CVD, specifically regarding domestic, occupational, recreational, and athletic activities. The "2011 Compendium of Physical Activities: A Second Update of Codes and MET Values"⁵⁶ and its associated web link (<http://links.lww.com/MSS/A82>) provide 821 codes that reflect 21 major headings, numerous specific activities and their detailed descriptions, and associated MET values that can be used to identify the energy cost associated with a given activity. By using the exercise test to measure peak exercise capacity in METs and evaluate the heart rate, blood pressure and symptomatic responses to peak and submaximal MET levels, the clinician can couple this information with that derived from the compendium to counsel patients on their ability to perform a broad spectrum of activities and tasks. It is important to realize, however, that the exercise test does not yield information regarding the patient's ability to perform sustained tasks for long periods, nor does it take into account the environmental conditions (e.g., temperature, humidity, altitude and wind) in which the activity is performed. Hence data from the exercise test and the compendium can serve only as a guide to prudent activity counseling. The patient must be made aware of these other factors and be instructed to use subjective symptoms scales (e.g., Borg Scale of Perceived Exertion)¹ to further tailor their activity performance.

Exercise training programs are designed to either maintain or improve fitness and include the prescriptive components of intensity, duration, frequency, and modality. Details regarding the exercise prescription for patients with CVD are provided elsewhere.² For patients with CVD, the *intensity* of dynamic aerobic exercise is usually determined from the results of a pretraining exercise test by using either of the following methods: 40% to 80% of peak exercise capacity using the *heart rate reserve* method (peak minus resting heart rate multiplied by percent intensity plus resting heart rate) and, in patients who have performed a CPX, the heart rate at 40% to 80% of the measured peak $\dot{V}O_2$. Intensity may be modified further by using the subjective perceived exertion scale at a rating of 11 to 16 on a scale of 6 to 20.¹ In patients with an ischemic response during exercise, the intensity should be prescribed at a heart rate that is at least 10 beats below the ischemic threshold (i.e., the heart rate at which ischemic ST depressions and/or typical angina begins to occur). The goal *duration* of exercise at the prescribed intensity is generally 20 to 60 minutes per session at a *frequency* of 3 to 5 days per week. Training *modalities* should ideally incorporate exercises that include rhythmic, large muscle group activities of both the upper and lower extremities with varying types of exercise equipment.

Emerging data on aerobic interval training (AIT) offer promise for patients with CVD. AIT involves alternating 3- to 4-minute periods of exercise at very high intensity (90% to 95% of the peak heart rate) with exercise at moderate intensity (60% to 70% of the peak heart rate). When such training is performed for approximately 40 minutes, 3 times per week, studies demonstrate greater improvements in peak $\dot{V}O_2$, endothelial function, and metabolic parameters than with standard continuous, moderate-intensity exercise.^{57,58} Although AIT has long been used in athletic training, it cannot yet be recommended for patients with CVD until further data regarding safety and efficacy are available.

Disability Assessment

The U.S. Social Security Administration defines disability as "the inability to engage in any substantial gainful activity by reason of any medically determinable physical or mental impairment(s) which can be expected to result in death or which has lasted or can be expected to last for a continuous period of not less than 12 months."⁵⁹ In several cardiovascular conditions, disability is not based solely on the diagnosis but also on the functional limitations imposed by the condition. Hence exercise testing plays an integral role in the determination of disability for several cardiovascular conditions, including chronic heart failure, ischemic heart disease, congenital heart disease, PAD, and valvular heart disease. The Institute of Medicine convened a panel of experts to provide recommendations for updating the social security listings for cardiovascular conditions.⁵⁹ Although each of the aforementioned conditions have specific criteria to define the condition, functional disability in almost all of them is defined by the inability to attain a peak $\dot{V}O_2$ of 15 mL/kg/min (or 5 METs) on a symptom-limited

TABLE 13-14 Chest Pain Unit: Patient Selection, Testing Procedure, and Endpoints

Patient Selection Criteria
Able to exercise
ECG: Normal or minor ST-T changes
Hemodynamically stable, no arrhythmia
Negative cardiac injury markers
Procedure
Bruce or modified Bruce protocol
Endpoints
Symptom limited
Ischemia (≥ 0.10 mV of horizontal ST-segment depression or elevation)
Decreased blood pressure (≥ 10 mm Hg systolic) during the exercise test
Result
Positive: ≥ 0.10 mV of horizontal ST-segment depression
Negative: No exercise-induced abnormalities at 85% MPPHR
Nondiagnostic: $\geq 85\%$ MPPHR with no electrocardiographic evidence of ischemia

MPPHR = maximum predicted heart rate.

**TABLE 13-15 Exercise Test Criteria for Determination of Disability in Patients with Specific Cardiovascular Conditions**

CARDIOVASCULAR CONDITION	SOCIAL SECURITY CRITERIA	INSTITUTE OF MEDICINE RECOMMENDATIONS
Chronic heart failure	Inability to attain 5 METs because of symptoms of dyspnea, fatigue, palpitations, or chest discomfort; frequent or complex ventricular ectopy; >10 mm Hg decrease in systolic blood pressure during graded exercise; signs caused by inadequate cerebral perfusion	Exercise testing in chronic heart failure is safe; CPX testing requires less subjective endpoint interpretation and uses the criteria of a peak $\dot{V}O_2$ of <15 mL/kg/min with a respiratory exchange ratio of >1.1 or <5 METs on a standard treadmill test without gas exchange; frequent exercise-induced ventricular ectopy alone should not be listed as a criterion
Ischemic heart disease	Exercise tolerance testing demonstrating ischemia or ≥ 10 mm Hg fall in systolic blood pressure at ≤ 5 METs	Additional specific criteria when stress imaging tests are used
Peripheral arterial disease	$\geq 50\%$ decrease in systolic blood pressure at the ankle from resting levels that requires ≥ 10 min to recover	
Congenital heart disease (adults)	Intermittent right-to-left shunting leading to cyanosis and an arterial PO_2 of ≤ 60 mm Hg at ≤ 5 METs	Intermittent right-to-left shunting with pulse oximetry of $\leq 85\%$ at ≤ 5 METs Exercise capacity with a peak $\dot{V}O_2$ of <15 mL/kg/min or <5 METs
Pulmonary hypertension	No previous criteria	Exercise capacity <5 METs
Valvular heart disease	No previous criteria	Exercise capacity <5 METs

TABLE 13-16 Gardner Testing Protocol for Patients with Peripheral Arterial Disease

STAGE	SPEED/GRADE	METs
1	2 mph/0%	2.5
2	2 mph/2%	3.1
3	2 mph/4%	3.6
4	2 mph/6%	4.2
5	2 mph/8%	4.7
6	2 mph/10%	5.3
7	2 mph/12%	5.8
8	2 mph/14%	6.4
9	2 mph/16%	6.9
10	2 mph/18%	7.5

Each stage is 2 minutes in duration.

From Gardner AW, Skinner JS, Cantwell BW, Smith LK: *Progressive vs single-stage treadmill tests for evaluation of claudication*. *Med Sci Sports Exerc* 23:402, 1991.

treadmill or stationary cycle test. Details regarding exercise test criteria for specific cardiovascular conditions as recommended by the Institute of Medicine are outlined in [Table 13-15](#).

Assessment of Peripheral Arterial Disease

Exercise testing can be performed in patients with PAD to further establish the diagnosis via noninvasive techniques, particularly in patients with calf pain and borderline ankle-brachial indices (ABIs; 0.91 to 1.0), and to objectively evaluate functional limitations imposed by PAD and the subsequent response to therapies ([see Chapter 58](#)). Assessment of the time to initial claudication symptoms (*claudication onset time*) and the *peak exercise time* to maximum tolerated calf pain should be done by using a gradual graded exercise treadmill (such as the Gardner protocol [[Table 13-16](#)]). For functional assessment, the 6-minute walk test ([see Table 13-8](#)) can also be used; during this test both time and distance are measured to onset and to peak calf pain.

The postexercise ABI can provide additional diagnostic information and is done by measuring the ABI in both ankles at rest ([see Chapters 11 and 58](#)) and again immediately after exercise. During leg exercise, systolic blood pressure normally increases in the arms

but decreases in the ankles because of the peripheral vasodilation that occurs in exercising leg muscles. Hence this leads to a mild decrease in the ABI in healthy patients that returns to normal within 1 to 2 minutes of recovery. In patients with PAD, ankle pressure decreases even more, thereby leading to a further decrease in the ABI and also a prolonged recovery time. Several diagnostic criteria have been proposed and include greater than a 5% drop in postexercise ABI from resting levels, postexercise ABI lower than 0.9, greater than a 30-mm Hg drop in systolic blood pressure at the ankle, and recovery time to baseline ABI longer than 3 minutes.⁶⁰

Evaluation of Patients with Diabetes

CAD remains the most common cause of morbidity and mortality in patients with diabetes mellitus ([see Chapter 61](#)). In recent years, strategies for the treatment of CAD in patients with diabetes have undergone much evolution such that regardless of symptoms or documented CAD, diabetic patients are treated with preventive therapies. In this context, the ability to specifically identify diabetic patients with disease who will benefit from more aggressive and, perhaps, invasive therapies remains a challenge. A comprehensive review of screening methods to detect CAD in patients with diabetes is found elsewhere.⁶¹ Exercise electrocardiographic testing has similar diagnostic sensitivity ($\approx 60\%$) and specificity ($\approx 80\%$) for diabetic patients with angina as for nondiabetic patients. It can also identify a subgroup of asymptomatic diabetic patients who have significant CAD as defined by angiography and, more importantly, in lower-risk asymptomatic diabetic cohorts may offer short-term prognostic reassurance to those with negative test results. However, considerable prognostic power of the exercise electrocardiographic test lies beyond the ST-segment response. Poor exercise capacity and slow HRR in diabetic patients are markers of an adverse outcome. The value of the Duke prognostic score in patients with diabetes has not been well studied, and unlike the Morise score³² and the Cleveland Clinic Foundation risk score,³³ it did not specifically address the presence of diabetes in the original cohort study. Hence at the present time the Morise and Cleveland Clinic scores are more appropriate to apply in patients with diabetes who have normal resting electrocardiographic findings and undergo exercise electrocardiography.

At present, evidence is inadequate for recommending routine screening of asymptomatic diabetic patients with an exercise ECG. The American Diabetes Association standards of medical care⁶² concluded that in asymptomatic patients, routine screening for CAD is not recommended, even before initiation of an exercise training

program, because it does not improve outcomes as long as risk factors for CVD are treated. However, cardiac testing should be performed for further evaluation of those with (1) typical or atypical cardiac symptoms and/or (2) abnormal findings on a resting ECG. These recommendations have arisen from the observation that intensive medical therapy, which would be indicated in any case for diabetic patients at high risk for CVD, appears to provide similar outcomes as invasive revascularization, hence raising the question of how the results of screening would change management. This position is supported by data from the DIAD (Detection of Ischemia in Asymptomatic Diabetics) study, which evaluated 1123 patients with type 2 diabetes and no symptoms of CAD. They were randomly assigned to be screened with adenosine stress radionuclide myocardial perfusion imaging (MPI) or not to be screened ([see Chapter 16](#)). Cardiac death and nonfatal myocardial infarction event rates were low in both groups (2.7% versus 3%) over a period of 4.8 years and not significantly reduced by MPI screening for myocardial ischemia. It is important to note that during the course of this study there was a significant and similar increase in primary medical prevention in both groups.⁶³

ACKNOWLEDGMENT

The authors wish to acknowledge the previous contributions of Dr. Bernard R. Chaitman, which have laid the foundation for this chapter.

GUIDELINES

Exercise Electrocardiographic Testing

Gary J. Balady and Anthony P. Morise

For almost 30 years, guidelines for clinical exercise electrocardiographic testing have been published and continually updated by the American Heart Association (AHA), jointly within clinical practice guidelines by the AHA and the American College of Cardiology (ACC), and by the American College of Sports Medicine (ACSM). The latest revisions of the AHA's exercise standards for testing and training¹ and the ACSM's guidelines for exercise testing² provide the most current comprehensive and detailed information regarding the technical aspects of exercise electrocardiographic testing, standards for the performance and interpretation of electrocardiograms (ECGs), and guidance regarding the diagnostic and prognostic usefulness of such tests. However, the ACC/AHA clinical practice guidelines on exercise testing,³ which provide specific classes of recommendations and levels of scientific evidence to support these recommendations (see later), were last revised in 2002 with no further plans for an update because specific recommendations regarding exercise electrocardiographic testing are now incorporated into recent revisions of all relevant disease-based ACC/AHA clinical practice guidelines.

The section that follows presents recommendations collated in tabular form from the latest updates of the disease-based ACC/AHA clinical practice guidelines in which exercise electrocardiographic testing is specifically addressed (i.e., coronary artery disease [CAD], peripheral arterial disease [PAD], valvular heart disease, heart failure and transplantation, hypertrophic cardiomyopathy, heart rhythm disorders, and adult congenital heart disease). Recommendations for the use of stress imaging tests are presented elsewhere in this textbook.

CLINICAL PRACTICE GUIDELINES

The ACC/AHA clinical practice guidelines are systematically developed statements designed to assist physician and patient decisions about appropriate health care for specific clinical circumstances.⁴ They were derived from available randomized controlled trials and other clinical trials, meta-analyses, and registry data to provide evidence-based standards of care. Recommendations are presented in four levels that reflect the benefit of the procedure relative to the risk or informational yield. In a *class I* recommendation, the benefit greatly outweighs the risk, and thus the procedure is *recommended*;

whereas in a *class III* recommendation, the procedure has no benefit and may in fact cause harm, and thus the procedure is *not recommended*. For *class II* recommendations, the benefit appears to be greater than the risk, and the procedure is considered *reasonable to perform* (IIa) or *may be considered* (IIb). The three levels of scientific evidence that support the recommendations are categorized from A to C. *Level A* evidence includes multiple population risk strata evaluated with a general consistency of direction and magnitude of effect and is based on multiple randomized clinical trials or meta-analyses, whereas *level C* evidence contains very limited population risk strata evaluated and is based largely on the consensus opinion of experts. *Level B* contains evidence from limited populations and is based on data derived from a single randomized trial or nonrandomized studies.

The ACC, along with the AHA and several specialty and subspecialty societies, has begun to develop and publish “appropriate use criteria” (AUC) for diagnostic tests and procedures that are used in the care of patients with known or suspected cardiovascular diseases. These documents reflect an ongoing effort of the ACC to critically and systematically create, review, and categorize clinical situations in which such procedures may be used. It is anticipated that the AUC will have an impact on physician decision making, test performance, and reimbursement policy, as well as on guidance for future research. At this time there are no specific AUC for exercise electrocardiographic testing.

CLINICAL INDICATIONS FOR EXERCISE TESTING

Coronary Artery Disease

The ACC/AHA guidelines address the use of the exercise ECG in the diagnostic evaluation of asymptomatic persons or patients with chest pain who are deemed to have an intermediate likelihood of obstructive CAD (see [Table 13-11](#)) and in the management of patients with stable CAD. These indications are addressed in [Table 13G-1](#).

Exercise electrocardiographic testing can also be useful in the assessment of specific patients following myocardial infarction ([Table 13G-2](#)) and has limited usefulness in patients following percutaneous coronary intervention ([Table 13G-3](#)).

Peripheral Arterial Disease

Exercise electrocardiographic testing is useful in the diagnostic assessment of patients with suspected PAD and in the functional assessment of patients with known PAD. It is also useful for patients with PAD who are undergoing an exercise training program and in

TABLE 13G-1 Exercise Electrocardiographic Testing in the Diagnosis and Management of Asymptomatic Persons, Patients with Chest Pain, and Patients with Stable Coronary Artery Disease**Class I**

Standard exercise electrocardiographic testing is recommended to aid in the diagnosis of CAD in patients with an intermediate pretest probability of ischemic heart disease who have an interpretable ECG and at least moderate physical functioning or no disabling comorbidity. (*Level of evidence: A.*)

Standard exercise electrocardiographic testing is recommended for risk assessment in patients with stable ischemic heart disease who are able to exercise to an adequate workload and have an interpretable ECG. (*Level of evidence: B.*)

Standard exercise electrocardiographic testing is recommended in patients with known stable ischemic heart disease who have new or worsening symptoms not consistent with unstable angina and who have (1) at least moderate physical functioning and no disabling comorbidity and (2) an interpretable ECG. (*Level of evidence: B.*)

Class IIa

For patients with a low pretest probability of obstructive ischemic heart disease who do require testing, standard exercise electrocardiographic testing can be useful, provided that the patient has an interpretable ECG and at least moderate physical functioning or no disabling comorbidity. (*Level of evidence: C.*)

Class IIb

An exercise electrocardiographic test may be considered for assessment of cardiovascular risk in intermediate-risk asymptomatic adults (including sedentary adults considering starting a vigorous exercise program), particularly when attention is paid to nonelectrocardiographic markers such as exercise capacity. (*Level of evidence: B.*)

Standard exercise electrocardiographic testing performed at 1-year or longer intervals might be considered for follow-up assessment in patients with stable ischemic heart disease who have had previous evidence of silent ischemia or are at high risk for a recurrent cardiac event and are able to exercise to an adequate workload and have an interpretable ECG. (*Level of evidence: C.*)

In patients who have no new or worsening symptoms or no previous evidence of silent ischemia and are not at high risk for a recurrent cardiac event, the usefulness of annual surveillance exercise electrocardiographic testing is not well established. (*Level of evidence: C.*)

Class III

Standard exercise electrocardiographic testing is not recommended for the evaluation of CAD in patients who have an uninterpretable ECG or are incapable of at least moderate physical functioning or have disabling comorbidity. (*Level of evidence: C.*)

Standard exercise electrocardiographic testing should not be performed in patients with known stable ischemic heart disease who have new or worsening symptoms not consistent with unstable angina and who (1) are incapable of at least moderate physical functioning or have disabling comorbidity or (2) have an uninterpretable ECG. (*Level of evidence: C.*)

From Fihn SD, Gardin JM, Abrams J, et al: 2012 ACCF/AHA/ACP/AATS/PCNA/SCAI/STS guideline for the diagnosis and management of patients with stable ischemic heart disease. A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, and the American College of Physicians, American Association for Thoracic Surgery, Preventive Cardiovascular Nurses Association, Society for Cardiovascular Angiography and Interventions, and Society of Thoracic Surgeons. *Circulation* 126:e354, 2012; and Greenland P, Alpert JS, Beller GA, et al: 2010 ACCF/AHA guideline for assessment of cardiovascular risk in asymptomatic adults. A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation* 112:e584, 2010.

TABLE 13G-2 Exercise Electrocardiographic Testing in Patients with Acute Coronary Syndromes, Including ST-Elevation (STEMI) and Non-ST-Elevation Myocardial Infarction (NSTEMI)**Class I**

Noninvasive testing for ischemia should be performed before discharge to assess the presence and extent of inducible ischemia in patients with STEMI who have not undergone coronary angiography and do not have high-risk clinical features for which coronary angiography would be warranted. (*Level of evidence: B.*)

For patients with unstable angina or NSTEMI in whom an initial conservative strategy is selected and no subsequent features appear that would necessitate diagnostic angiography (recurrent symptoms/ischemia, heart failure, or serious arrhythmias), a stress test should be performed. (*Level of evidence: B.*)

Noninvasive stress testing is recommended before discharge in low-risk* patients who have been free of ischemia at rest or have low-level activity and have been free of heart failure for a minimum of 12 to 24 hours. (*Level of evidence: C.*)

Noninvasive stress testing is recommended in patients at intermediate risk* who have been free of ischemia at rest or have low-level activity and have been free of heart failure for a minimum of 12 to 24 hours. (*Level of evidence: C.*)

The choice of stress test is based on the resting ECG, ability to perform exercise, local expertise, and the technologies available. Treadmill exercise is useful in patients able to exercise in whom the ECG is free of baseline ST-segment abnormalities, bundle branch block, left ventricular hypertrophy, intraventricular conduction defect, paced rhythm, preexcitation, and digoxin effect. (*Level of evidence: C.*)

Class IIb

Noninvasive testing (exercise electrocardiographic testing) for ischemia might be considered before discharge to guide the postdischarge exercise prescription. (*Level of evidence: C.*)

*Low risk and intermediate risk have none of the following features: *History*—Accelerating tempo of ischemic symptoms in the preceding 48 hours; *Character of pain*—Prolonged ongoing (>20 minutes) pain or pain at rest; *Clinical findings*—Pulmonary edema, most likely caused by ischemia; new or worsening mitral regurgitation murmur, S₃ or new/worsening rales; hypotension, bradycardia, tachycardia; age older than 75 years; *ECG*—Angina at rest with transient ST-segment changes greater than 0.5 mm; bundle branch block, new or presumed new; sustained ventricular tachycardia; *Cardiac markers*—Elevated cardiac troponin T (TnT), troponin I (TnI), or creatine kinase MB fraction (e.g., TnT or TnI >0.1 ng/mL).

A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation* 127:e362, 2013; and Anderson JL, Adams CD, Antman EM, et al: ACCF/AHA 2007 guidelines for the management of patients with unstable angina/non ST-elevation myocardial infarction. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines for the Management of Patients With Unstable Angina/Non ST-Elevation Myocardial Infarction). Developed in collaboration with the American College of Emergency Physicians, the Society for Cardiovascular Angiography and Interventions, and the Society of Thoracic Surgeons; endorsed by the American Association of Cardiovascular and Pulmonary Rehabilitation and the Society for Academic Emergency Medicine. *Circulation* 116:Le148, 2007.

the evaluation of those with PAD following surgical or endovascular revascularization procedures ([Table 13G-4](#)).

Valvular Heart Disease

Exercise testing is useful for assessing functional capacity in patients with valvular heart disease, particularly those with regurgitant lesions. Even though exercise testing should not be performed in patients with severe symptomatic aortic stenosis, it may be useful in those with aortic stenosis when the symptoms are equivocal or uncertain ([Table 13G-5](#)). Stress echocardiographic testing has growing usefulness in the evaluation of patients with valvular heart disease and is discussed elsewhere in this textbook ([see Chapters 14 and 63](#)).

TABLE 13G-3 Exercise Electrocardiographic Testing Following Percutaneous Coronary Intervention

Class IIa

In patients entering a formal cardiac rehabilitation program after percutaneous coronary intervention, treadmill exercise testing is reasonable. (Level of evidence: C.)

Class III

Routine periodic stress testing of asymptomatic patients after percutaneous coronary intervention should not be performed without specific clinical indications. (Level of evidence: C.)

From Levine GN, Bates ER, Blankenship JC, et al: 2011 ACCF/AHA/SCAI guideline for percutaneous coronary intervention. A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines and the Society for Cardiovascular Angiography and Interventions. *Circulation* 124:e574, 2011.

TABLE 13G-4 Exercise Testing in Patients with Peripheral Arterial Disease

Class I

Exercise treadmill tests are recommended to provide the most objective evidence of the magnitude of the functional limitation of claudication and to measure the response to therapy. (Level of evidence: B.)

A standardized exercise protocol (either fixed or graded) with a motorized treadmill should be used to ensure reproducibility of measurements of pain-free walking distance and maximal walking distance. (Level of evidence: B.)

Exercise treadmill tests with measurement of pre-exercise and postexercise ankle-brachial index (ABI) values are recommended to provide diagnostic data useful in differentiating arterial claudication from nonarterial claudication ("pseudoclaudication"). (Level of evidence: B.)

Exercise treadmill tests should be performed in individuals with claudication who are to undergo exercise training (lower extremity PAD rehabilitation) to determine functional capacity, assess nonvascular exercise limitations, and demonstrate the safety of exercise. (Level of evidence: B.)

Class IIa

An exercise ABI measurement can be useful to diagnose lower extremity PAD in individuals who are at risk for lower extremity PAD and have a normal ABI (0.91 to 1.30), are without the classic symptoms of claudication, and have no other clinical evidence of atherosclerosis. (Level of evidence: C.)

The long-term patency of infrainguinal bypass grafts may be considered for evaluation in a surveillance program, which may include conducting exercise ABIs and other arterial imaging studies at regular intervals. (Level of evidence: B.)

The long-term patency of endovascular sites may be evaluated in a surveillance program, which may include conducting exercise ABIs and other arterial imaging studies at regular intervals (Level of evidence: B.)

Class IIb

A 6-minute walk test may be reasonable to provide an objective assessment of the functional limitation of claudication and response to therapy in elderly individuals or others not amenable to treadmill testing. (Level of evidence: B.)

From Hirsch AT, Haskal ZJ, Hertzler NR, et al: ACC/AHA 2005 practice guidelines for the management of patients with peripheral arterial disease (lower extremity, renal, mesenteric, and abdominal aortic). A collaborative report from the American Association for Vascular Surgery/Society for Vascular Surgery, Society for Cardiovascular Angiography and Interventions, Society for Vascular Medicine and Biology, Society of Interventional Radiology, and the ACC/AHA Task Force on Practice Guidelines (Writing Committee to Develop Guidelines for the Management of Patients With Peripheral Arterial Disease). Endorsed by the American Association of Cardiovascular and Pulmonary Rehabilitation; National Heart, Lung, and Blood Institute; Society for Vascular Nursing; TransAtlantic Inter-Society Consensus; and Vascular Disease Foundation. *Circulation* 113:e463, 2006.

Heart Failure and Transplantation

The ACC/AHA heart failure guidelines support the use of exercise electrocardiographic testing and cardiopulmonary exercise testing using gas exchange analysis for the evaluation of patients for cardiac transplantation or those who have concomitant pulmonary disease in whom the cause of dyspnea is unclear. Exercise testing is also useful in the development of an exercise prescription for patients with heart failure or following heart transplantation ([Table 13G-6](#)).

Hypertrophic Cardiomyopathy

Exercise testing is useful for risk stratification and functional assessment of patients with hypertrophic cardiomyopathy ([Table 13G-7](#)). Exercise echocardiography can provide additional information regarding the development or worsening of dynamic left ventricular outflow tract gradients and is discussed elsewhere in this textbook ([see Chapter 66](#)).

Heart Rhythm Disorders

Exercise electrocardiographic testing is useful in the evaluation of patients with heart rhythm disorders when the test is intended to diagnose exercise-induced arrhythmias or evaluate medical or ablative therapy. It is not recommended to be used in patients with unstable arrhythmias or high-degree atrioventricular block or for routine evaluation of young patients with isolated ectopic beats ([Table 13G-8](#)).

Adult Congenital Heart Disease

Exercise testing can be useful in selected patients with an atrial septal defect, congenital valvular and subvalvular aortic stenosis, coarctation of the aorta, congenitally corrected transposition of the great arteries, Ebstein anomaly, and patent ductus arteriosus. Sub-maximal exercise testing (e.g., 6-minute walk test) can be useful in

TABLE 13G-5 Exercise Electrocardiographic Testing in Patients with Valvular Heart Disease**Class I**

Exercise testing with Doppler or invasive hemodynamic assessment is recommended to evaluate the response of the mean mitral gradient and pulmonary artery pressure in patients with mitral stenosis when there is a discrepancy between resting Doppler echocardiographic findings and clinical symptoms or signs. (Level of evidence: C)

Class IIa

Exercise testing is reasonable in selected patients with asymptomatic severe valvular heart disease to (1) confirm the absence of symptoms, (2) assess the hemodynamic response to exercise, or (3) determine prognosis. (Level of evidence: B)

Exercise testing is reasonable to assess physiological changes with exercise and to confirm the absence of symptoms in asymptomatic patients with a calcified aortic valve and an aortic velocity 4.0 meters per second or greater or mean pressure gradient 40 mm Hg or higher. (Level of evidence: B)

Exercise testing should not be performed in symptomatic patients with AS when the aortic velocity is 4.0 meters per second or greater or mean pressure gradient is 40 mm Hg or higher. (Level of evidence: B)

Exercise hemodynamics with either Doppler echocardiography or cardiac catheterization is reasonable in symptomatic patients with chronic primary mitral regurgitation (MR) where there is a discrepancy between symptoms and the severity of MR at rest. (Level of evidence: B)

Exercise treadmill testing can be useful in patients with chronic primary MR to establish symptom status and exercise tolerance. (Level of evidence: C)

Class IIb

Exercise testing may be considered for the assessment of exercise capacity in patients with severe tricuspid regurgitation with no or minimal symptoms. (Level of evidence: C)

Class III

Exercise testing should not be performed in symptomatic patients with aortic stenosis when the aortic velocity is 4.0 meters per second or greater or mean pressure gradient is 40 mm Hg or higher. (Level of evidence: B)

Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC guideline for the management of patients with valvular heart disease: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 63:e57, 2014.

TABLE 13G-6 Exercise Electrocardiographic Testing in Patients with Heart Failure**Class IIa**

Maximal exercise testing with or without measurement of respiratory gas exchange and/or blood oxygen saturation is reasonable in patients with heart failure to help determine whether heart failure is the cause of exercise limitation when its contribution is uncertain. (Level of evidence: C)

Maximal exercise testing with measurement of respiratory gas exchange is reasonable to identify high-risk patients with heart failure who are candidates for cardiac transplantation or other advanced treatment. (Level of evidence: B)

Maximal exercise testing with or without measurement of respiratory gas exchange is reasonable to facilitate prescription of an appropriate exercise program for patients with heart failure. (Level of evidence: C)

From Hunt SA, Abraham WT, Chin MH, et al: 2009 focused update incorporated into the ACC/AHA 2005 guidelines for the diagnosis and management of heart failure in adults. TABLE 13G-7 Exercise Electrocardiographic Testing in Patients with Hypertrophic Cardiomyopathy**Class IIa**

Treadmill exercise testing is reasonable to determine functional capacity and response to therapy in patients with hypertrophic cardiomyopathy. (Level of evidence: C)

Treadmill testing with monitoring of the ECG and blood pressure is reasonable for sudden cardiac death risk stratification in patients with hypertrophic cardiomyopathy. (Level of evidence: B)

From Gersh BJ, Maron BJ, Bonow RO, et al: 2011 ACCF/AHA guideline for the diagnosis and treatment of hypertrophic cardiomyopathy. A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation* 124:e783, 2011.

TABLE 13G-8 Exercise Electrocardiographic Testing in Patients with Heart Rhythm Disorders**Class I**

In patients who experience symptoms related to atrial fibrillation during activity, the adequacy of heart rate control should be assessed during exercise, with adjustment of pharmacologic treatment as necessary to keep the rate in the physiologic range. (Level of evidence: C)

The following are included as indications for exercise testing in patients with atrial fibrillation but are not given a recommendation class or level of evidence:

- To reproduce exercise-induced atrial fibrillation
- To exclude ischemia before treatment of selected patients with a type IC antiarrhythmic drug

Exercise testing is recommended in adult patients with ventricular arrhythmias who have an intermediate or greater probability of having coronary heart disease by age, sex, and symptoms to provoke ischemic changes or ventricular arrhythmias. (Level of evidence: B)

Exercise testing, regardless of age, is useful for patients with known or suspected exercise-induced ventricular arrhythmias, including catecholaminergic ventricular tachycardia, to provoke the arrhythmia, achieve a diagnosis, and determine the patient's response to tachycardia. (Level of evidence: B)

Class IIa

Exercise testing can be useful for evaluating response to medical or ablation therapy in patients with known exercise-induced ventricular arrhythmias. (Level of evidence: B)

Class IIb

Exercise testing may be useful in patients with ventricular arrhythmias and a low probability of coronary heart disease by age, sex, and symptoms. (Level of evidence: C)

Exercise testing may be useful in the investigation of isolated premature ventricular complexes in middle-aged or older patients without other evidence of coronary heart disease. (Level of evidence: C)

Class III

Routine investigation of isolated ectopic beats in young patients
Uncontrolled cardiac arrhythmias causing symptoms or hemodynamic compromise
High-degree atrioventricular block

From Fuster V, Ryden LE, Cannom DS, et al: 2011 ACCF/AHA/HRS focused updates incorporated into the ACC/AHA/ESC 2006 guidelines for the management of patients with atrial fibrillation. **TABLE 13G-9 Exercise Electrocardiographic Testing in Patients with Congenital Heart Disease**

Atrial Septal Defect Class IIa Maximal exercise testing can be useful to document exercise capacity in patients with symptoms that are discrepant with the clinical findings or to document changes in oxygen saturation in those with mild or moderate pulmonary artery hypertension. (Level of evidence: C) Class III Maximal exercise testing is not recommended in patients with an atrial septal defect and severe pulmonary arterial hypertension. (Level of evidence: B) Aortic Stenosis Class IIa In asymptomatic adults younger than 30 years, exercise stress testing is reasonable to determine exercise capability, symptoms, and blood pressure response. (Level of evidence: C) Exercise stress testing is reasonable for patients with a mean Doppler gradient >30 mm Hg or peak Doppler gradient >50 mm Hg if they are interested in athletic participation or if clinical findings differ from noninvasive measurements. (Level of evidence: C) Exercise stress testing is reasonable for the evaluation of an asymptomatic young adult with a mean Doppler gradient >40 mm Hg or a peak Doppler gradient >64 mm Hg or when athletic participation or pregnancy is anticipated. (Level of evidence: C) Exercise stress testing can be useful to evaluate the blood pressure response or elicit exercise-induced symptoms in asymptomatic older adults with aortic stenosis. (Level of evidence: B) Class III Exercise stress testing should not be performed in symptomatic patients with aortic stenosis or those with a repolarization abnormality on the ECG or systolic dysfunction on the echocardiogram. (Level of evidence: C) Supravalvular Aortic Stenosis Class IIa Exercise testing, dobutamine stress testing, positron emission tomography, or stress sestamibi with adenosine studies can be useful to evaluate the adequacy of myocardial perfusion. (Level of evidence: C) Subvalvular Aortic Stenosis Class IIa Stress testing to determine exercise capability, symptoms, electrocardiographic changes or arrhythmias, or an increase in the left ventricular outflow tract gradient is reasonable in the presence of otherwise equivocal indications for intervention. (Level of evidence: C)	<p>Exercise testing, dobutamine stress testing, positron emission tomography, or stress sestamibi with adenosine studies can be useful to evaluate the adequacy of myocardial perfusion. (Level of evidence: C)</p> <p>Coarctation of the Aorta Class IIb Routine exercise testing may be performed at intervals determined by consultation with the regional adult congenital heart disease center. (Level of evidence: C)</p> <p>Congenitally Corrected Transposition of the Great Arteries Class I Exercise testing as part of routine evaluation.</p> <p>Ebstein Anomaly The following is included as an indication for exercise testing in patients with Ebstein anomaly but is not given a recommendation class or level of evidence. Patients with the Ebstein anomaly and marked cardiomegaly may complain of few symptoms despite marked limitation. Exercise testing will demonstrate functional limitation and should be included as part of the regular assessment of these patients. Exercise testing should include monitoring of oxygen saturation because exercise-induced cyanosis may occur.</p> <p>Patent Ductus Arteriosus Class III Maximal exercise testing is not recommended in patients with patent ductus arteriosus and significant pulmonary arterial hypertension. (Level of evidence: B)</p> <p>Congenital Heart Disease with Pulmonary Arterial Hypertension Class II It is reasonable to include a 6-minute walk test or similar nonmaximal cardiopulmonary exercise test as part of the functional assessment of patients with congenital heart disease and pulmonary arterial hypertension. (Level of evidence: C)</p>

APPROPRIATE USE CRITERIA, 252

Echocardiography remains the most commonly used and comprehensive cardiac imaging modality and is generally considered the first test of choice for assessing cardiac structure and function in most clinical situations. When compared with other imaging methods, echocardiography can be performed quickly, with minimal patient inconvenience or discomfort, and provides immediate clinically relevant information at relatively low cost. Echocardiography provides detailed data on cardiac structure, including the size and shape of cardiac chambers, as well as the morphology and function of cardiac valves. Furthermore, the real-time nature of echocardiography makes it uniquely suited to noninvasive assessment of systolic and diastolic function and intracardiac hemodynamics. In most echocardiography laboratories, standard transthoracic echocardiography (TTE) is complemented by transesophageal echocardiography (TEE), which offers improved resolution because of closer proximity of the transducer to cardiac structures, and by stress echocardiography, which is routinely used to assess myocardial ischemia and valvular function with exercise. Technical advancements in echocardiography over the past several decades have led to progressively improved diagnostic capabilities, including major advances in three-dimensional echocardiography, miniaturization of equipment leading to handheld echocardiography units, and contrast echocardiography for better cavity visualization and assessment of myocardial perfusion.

Because two-dimensional echocardiography is not a tomographic technique like cardiac computed tomography (CT) or cardiac

magnetic resonance (CMR) (see Chapters 17 and 18), acquisition of ultrasound images is dependent on an operator—either a sonographer or a physician—applying an ultrasound transducer to a patient's chest. Both acquisition and interpretation of echocardiograms require substantial training and skill. Thus echocardiography is best described as an “examination” rather than a “test.” Although cardiologists receive this training routinely, a growing number of noncardiologists, including emergency physicians, anesthesiologists, intensivists, and others, are increasingly using echocardiography in their practice. The advent of small, handheld ultrasound devices, which complement the physical examination, will further open this field to a wide array of practitioners who may not currently practice echocardiography. Knowledge of its basic principles, uses, and limitations is becoming essential for all physicians who care for patients with cardiovascular problems.

PRINCIPLES OF ULTRASOUND AND INSTRUMENTATION

Principles of Image Generation

Echocardiography is based on the standard principles of ultrasound imaging in which high-frequency sound waves in the 1- to 10-MHz range are emitted from piezoelectric crystals housed in a transducer,

traverse through internal body structures, interact with tissues, reflect back to the transducer, and are then processed by microcomputers to generate an image. An understanding of the physical principles that underlie echocardiography is essential to understanding its usefulness and limitations.¹

Ultrasound machines calculate the time required for sound waves to reflect from structures and return to the transducer, thereby determining the depth of reflecting structures. This information is used to generate scan lines that comprise data on both location (depth of reflection) and amplitude (intensity of reflection). Early ultrasound equipment projected a single “beam” of ultrasound, which resulted in a single scan line that could be “painted” across a moving paper or screen, with depth being depicted on the vertical axis and time on the horizontal axis. This method, known as M-mode (for “motion”) echocardiography (Fig. 14-1, right panel), has largely been replaced by two-dimensional imaging (Fig. 14-1, left panel), although it is still used routinely and considered ideal for making linear measurements and for assessments that require high temporal resolution.

Two-dimensional imaging uses electronically steered, phased-array transducers with multiple (currently up to 512) emitting and receiving elements embedded in the transducer (Fig. 14-2). These devices emit pulses of ultrasound in an ordered sequence and sequentially listen for returning echoes, referred to as the pulse-echo principle. The sequence occurs repeatedly to generate moving images. The rate at which these pulses are emitted, termed the *pulse repetition frequency* (PRF), is limited by the finite speed of ultrasound in tissues (≈ 1540 meters/sec) and the depth of the tissues being interrogated because time is required for the ultrasound pulse to return to the transducer. Nevertheless, improvements in processing speed have allowed “frame” rates to reach speeds higher than 100 per second. For most imaging applications, frame rate, a determinant of temporal resolution, can be increased by narrowing the scan sector, imaging at shallower depths, and reducing scan line density. Three-dimensional echocardiography extends the phased-array concept to a planar waffle-like grid or matrix-array transducer and allows both simultaneous multiplanar two-dimensional imaging and true volumetric three-dimensional imaging and rendering (see the section [Three-Dimensional Echocardiography](#)).

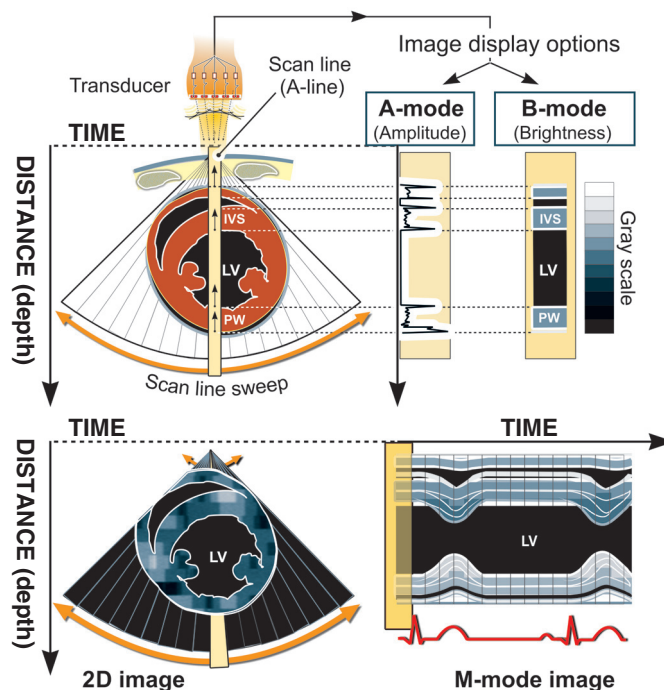

FIGURE 14-1 Generation of ultrasound images. An ultrasound pulse transmitted from piezoelectric elements housed in a transducer (upper left) reflects off structures and returns to the transducer. These signals are processed and displayed based on their amplitudes (upper right). Note that echoes with the highest amplitudes emerge from tissue interfaces such as the pericardial-pleural and endocardial-blood borders (upper panels). In original A-mode scans, such signals are visualized as amplitude spikes (upper right). On B-mode, the echo amplitudes are displayed via gray scale—with the least reflective tissues appearing black (upper right). B-mode images can then be displayed in one dimension over time—M (motion)-mode (bottom right) or as a two-dimensional cross-sectional image (bottom left). IVS = interventricular septum; LV = left ventricle; PW = posterior wall. (Modified from Bulwer BE, Rivero JM [eds]: *Echocardiography Pocket Guide: The Transthoracic Examination*. Burlington, Mass, Jones & Bartlett Learning, 2011, 2013. Reprinted with permission.)

FIGURE 14-2 Phased-array transducer operation. Modern echocardiography transducers scan through a relatively wide scan sector by steering the electronic beam across the scan plane (center). During transmission (left), electronic time delays in firing the piezoelectric elements of the transducer sweep the scan line across the scan plane. During reception (right), the returning echo signals received by each transducer element must be time-shifted or phased before being summated and processed. (Modified from Bulwer BE, Shernan SK, Thomas JD: *Physics of echocardiography*. In Savage RM, Aronson S, Shernan SK [eds]: *Comprehensive Textbook of Perioperative Transesophageal Echocardiography*. Philadelphia, Wolters Kluwer: Lippincott, Williams & Wilkins, 2009, pp 1-41.)

Physical Principles of Ultrasound

The physical characteristics of ultrasound are integral to the generation of images. The wavelength of the ultrasound used, which is inversely related to ultrasound frequency, is the principal determinant of axial imaging resolution, which is approximately half the wavelength. The higher the ultrasound frequency or the shorter the wavelength, the higher the spatial resolution and the greater the ability to discern structures. Imaging resolution is also dependent on the depth of the structure being interrogated. Even though higher frequencies are capable of increased resolution, this occurs at the expense of reduced tissue penetration, which decreases with increasing ultrasound frequency. Higher frequencies can be used in pediatric imaging or TEE, where penetration is less of an issue because of proximity of the transducer to the structures being interrogated, or when interrogating near-field structures, such as the apex of the heart from the apical view or right ventricular (RV) structures from parasternal views.

The speed of ultrasound through body tissues, which averages 1540 meters/sec, essentially the same as its speed through water, varies minutely as ultrasound waves traverse various body constituents. Slight differences in ultrasound speed through different body tissues result in impedance mismatches at the interfaces between tissues, which produces the *specular* reflections that account for the distinct visualization of tissue interface borders, such as the endocardium and epicardium of the heart. The most intense reflections occur at the interfaces between tissues when ultrasound strikes these interfaces perpendicularly. When ultrasound encounters inhomogeneous tissue regions, such as myocardial muscle, liver, or other tissues, multidirectional reflection, or *backscatter*, occurs and results in speckled-appearing images. The combination of specular reflections and backscatter, together with the unique interactions between ultrasound and tissue such as refraction, interference, and attenuation, contributes to the characteristic gray-scale appearance of ultrasound images. Ultrasound penetrates poorly through air and bone, which is one of the greatest challenges to echocardiography because the heart is surrounded by the lungs and the rib cage. This major limitation and the need to minimize its impact during image acquisition underscore the importance of the operator's skill and the advantages of the TEE approach in certain clinical situations.

Several advances in the past decade have improved the quality of ultrasonic imaging. Increases in the number of elements in phased-array transducers have increased the number of scan lines and hence lateral resolution. Tissue harmonic imaging, which uses second harmonics arising directly from the insonified tissues, has significantly improved the signal-to-noise ratio and substantially improved the definition of tissue interfaces, in particular, enhancement of endocardial border definition (Fig. 14-3). By listening for returning ultrasound signals that are twice the frequency of the emitted ultrasound, second-harmonic imaging favors the higher-frequency vibrations from tissues and effectively filters out the weaker noisy signals from cardiac chambers.

PRINCIPLES OF DOPPLER IMAGING

In addition to generating images of cardiac structures, ultrasound can be used to interrogate the velocity of blood flow through the heart and to quantify movement of the cardiac chambers. These techniques are based on the Doppler principle, which states that the frequency of any waveform emitted from a moving object will be perceived as higher than or lower than the actual frequency,

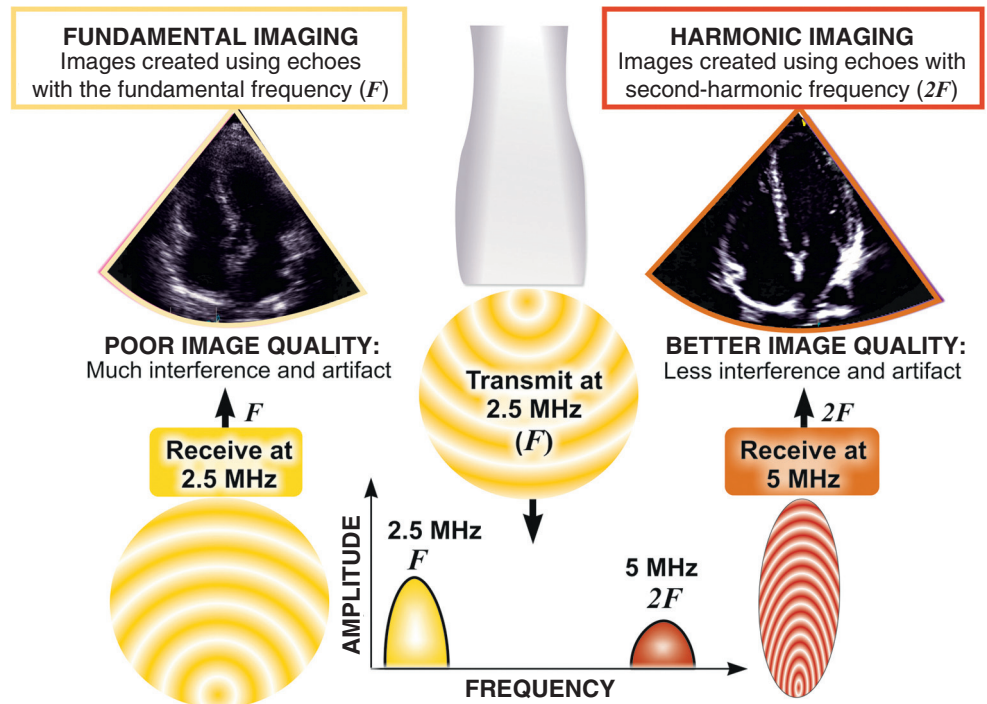

FIGURE 14-3 Tissue harmonic imaging. Tissue harmonic imaging improves image quality by using second-order harmonics in which ultrasound at a specific frequency causes tissues to vibrate at twice the frequency. By listening for these higher frequencies of returning echoes, the signal-to-noise ratio is dramatically improved. Images created by using second-harmonic imaging are less plagued by acoustic noise and artifacts, with much improved tissue definition (right). (Modified from Bulwer BE, Shernan SK, Thomas JD: *Physics of echocardiography*. In Savage RM, Aronson S, Shernan SK [eds]: *Comprehensive Textbook of Perioperative Transesophageal Echocardiography*. Philadelphia, Wolters Kluwer: Lippincott, Williams & Wilkins, 2009, pp 1-41.)

depending on whether the object is moving toward or away from the observer. Ultrasound that is emitted at a particular frequency and then reflected from moving red blood cells will return to the transducer at a slightly different frequency than that at which it was emitted: either higher if the flow is toward the transducer or lower if the flow is away from the transducer (Fig. 14-4). This difference between the frequency emitted and that received, termed the *Doppler frequency shift*, is dependent on the speed of ultrasound through the medium and the velocity of blood flow and is summarized by the Doppler equation

$$f_d = 2f_t V (\cos\theta)/c$$

where f_d is the Doppler shift frequency, f_t is the transmitted ultrasound frequency, V is the velocity of blood flow, c is the speed of ultrasound in the tissue, and θ represents the angle of flow relative to the ultrasound beam (angle of insonation).

Pulsed-Wave and Continuous-Wave Doppler

The two principal types of Doppler imaging are pulsed-wave (PW) and continuous-wave (CW) Doppler (Fig. 14-5). In PW Doppler (Fig. 14-5, left panel), discrete pulses of ultrasound reflect off moving structures (i.e., red blood cells moving through the heart) and return to the transducer. By gating (i.e., defining a specific time window in which to listen to the reflected signal), this technique can be used to assess the velocity of blood flow at a particular depth within the heart. When an operator places a cursor on the two-dimensional ultrasound image at a particular location, the equipment will assess the velocity at that particular location. Because these pulses take time to reflect and return to the transducer, they cannot be transmitted too frequently or the equipment will fail to discern whether a given pulse—or a later pulse—has returned and the velocity information obtained at that depth will be ambiguous. The PRF is essentially the sampling rate; the higher the blood flow velocity, the higher the

FIGURE 14-4 The Doppler principle and Doppler frequency shift. Echoes reflected from blood cells moving toward the transducer will return at a higher frequency than the transmitted ultrasound pulse (**upper panels**). The opposite is seen with blood moving away from the transducer (**lower panels**). Doppler echocardiography instruments harness this shift in frequency—the Doppler frequency shift—to derive blood flow velocities. The direction of flow is displayed graphically as a time-velocity spectrum above or below the baseline (in spectral Doppler) or as color-coded velocities with color flow Doppler.

FIGURE 14-5 The PW Doppler technique uses a single piezoelectric element that generates the pulse, interrogates a small sample volume at a specific depth, and receives the echoes emerging thereof (**left panel**). The CW Doppler technique uses separate elements that continuously transmit pulses and receive echoes indiscriminately across a large sample volume (**right panel**).

frequency of the Doppler shift and hence the higher the sampling rate needed to accurately sample that shift. From a practical standpoint, these physical principles determine the upper limit of velocities that can be interrogated accurately with PW Doppler. The Nyquist limit refers to the maximum velocity that can be accurately quantified within a given sample volume and is directly related to the PRF, which in turn is inversely related to the distance from the sample volume to the transducer (**Fig. e14-1**).

With CW Doppler (see **Fig. 14-5**, right panel) a dedicated piezoelectric element continuously emits ultrasound and a separate element simultaneously continuously receives the returning signals. Because the ultrasound tone is continuous rather than pulsed, depth

localization cannot be ascertained from the signal received. However, unlike the situation with PW Doppler, no limit is imposed on the velocities discernible with this technique. Thus PW Doppler is primarily used to assess flow with relatively low velocity (typically <1.5 meters/sec) present at a specific depth location, whereas CW Doppler is used to assess higher velocities (typically >1.5 meters/sec) but without such depth specificity.

Color Flow Doppler

Color flow Doppler is a PW Doppler-based technique in which the velocities in a region of interest are encoded with colors that represent both mean velocities and directionality of the flow superimposed on a two-dimensional image with a color map (**Fig. 14-6**). By convention, flow that is moving away from the transducer is encoded in blue, and flow that is moving toward the transducer is encoded in red. Because color flow Doppler is a form of PW Doppler, it is subject to aliasing. High velocities and turbulent flow, when a wide range of velocities exist, appear as a multicolored mosaic pattern (usually green and yellow). In some systems the variance in the velocities relative to the mean is color-coded in superimposed shades of green. Color flow Doppler allows direct real-time visualization of the movement of blood in the heart and is particularly useful in identifying blood flow acceleration and turbulence. Hence color flow Doppler is exceptionally adept at delineating regurgitant lesions, which tend to be relatively high-velocity flow and turbulent, and discrete stenoses, in which blood flow accelerates.

Blood Flow Profiles and Doppler Signals

Blood flow through the heart and major blood vessels can be laminar or turbulent. Laminar, or streamlined, flow occurs when the direction and velocity of flow throughout a region are uniform (**Fig. 14-7**). Blood flow through a normal heart and great vessels is predominantly laminar, even across valves. The spectral Doppler flow signal observed when interrogating laminar flow is characterized by a

FIGURE e14-1 Velocities derived from Doppler frequency shifts are extracted through sampling and transformation (Fourier) before being graphically displayed. PW Doppler is subject to the limitation of aliasing when the Nyquist criterion or limit is exceeded, hence limiting the velocities that can be accurately depicted with this modality. According to digital sampling theory, sampling frequency must be at least twice the frequency of the sampled waveform. In Doppler ultrasound, the sampling rate must be high enough to sample the Doppler shift, which is the difference between the ultrasound frequency emitted by the transducer and the ultrasound frequency returning to the transducer. As shown by the Doppler equation, $f_d = \frac{2f_t V \cos \theta}{C}$, this difference, the Doppler frequency shift, is directly related to the velocity of the flow

being assessed. The sampling rate is essentially the PRF. If this rate is too low, the waveform being sampled (in this case the Doppler shift waveform) cannot be approximated by the system, and the waveform will be sampled ambiguously. PW Doppler can accurately sample and reconstruct lower blood velocities (from the Doppler shift) with no ambiguity (aliasing) (**upper panels**). The frequency at which waveform sampling will become ambiguous is referred to as the Nyquist limit and is half the PRF. Thus when velocities being assessed exceed the Nyquist limit, the system cannot accurately determine these velocities, and aliasing occurs (**lower panels**). These higher aliased velocities will appear on the opposite side of the baseline on the spectral Doppler display or will result in mosaic patterns in color flow Doppler imaging. How can this problem be minimized? Simply increasing the PRF works only up to a certain point because the farther the ultrasound pulse has to travel, the greater the time delay must be between pulses to avoid ambiguity. Newer ultrasound machines have added the ability to increase the PRF beyond the Nyquist limit, thereby reducing aliasing. Referred to as high-PRF Doppler imaging, pulses are emitted without waiting for the original pulses to return to the transducer. This allows an unaliased signal at the expense of range ambiguity. The technique is meant to be used in conjunction with standard PW Doppler, with the operator determining the region of highest velocity along a scan line with PW Doppler and then switching to the high-PRF mode to determine this velocity.

FIGURE 14-6 Color flow Doppler. By convention, mean velocities moving toward the transducer are color-coded in red and those moving away from the transducer are encoded in blue. High velocities and turbulent flow, which are subject to aliasing as with other forms of PW Doppler, appear as a multicolored mosaic pattern (usually green and yellow). These colors are superimposed on the cross-sectional image. The color-velocity scale depicts increasing velocities in either direction away from the baseline, with higher velocities appearing in progressively lighter hues. LA = left atrium; LAA = left atrial appendage; LV = left ventricle; PA = pulmonary artery; RA = right atrium; RV = right ventricle. (Modified from Bulwer BE, Rivero JM [eds]: *Echocardiography Pocket Guide: The Transthoracic Examination*. Burlington, Mass, Jones & Bartlett Learning, 2011, 2013, p 156. Reprinted with permission.)

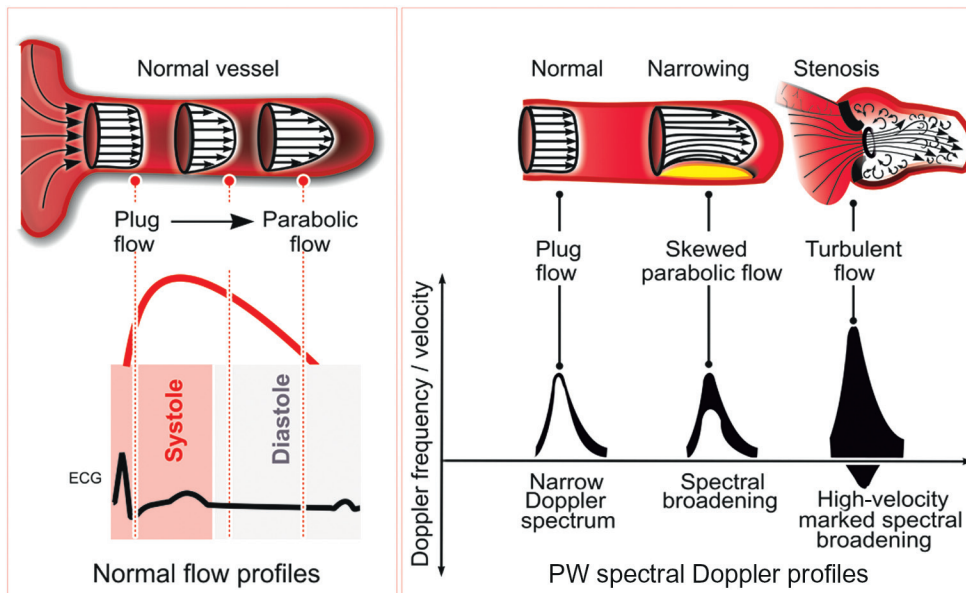

FIGURE 14-7 Flow velocity profiles and spectral Doppler representations. **Left**, During the cardiac cycle, most intra-cardiac and large arterial flows exhibit a laminar flow profile that is initially termed “plug flow” but progresses to a more parabolic profile because of drag force and blood viscosity. **Right**, The narrowest range or spectrum of flow velocities is seen during the initial phases of systole or when valves open (plug flow). The spectrum of blood flow velocities progressively broadens with progressive vessel narrowing. On spectral Doppler this is seen as spectral broadening. Turbulent flows demonstrate the widest range of flow velocities, including multidirectional flow. On the spectral Doppler display this demonstrates the widest range of flow velocities, which appear as increased velocities shown both above and below the baseline. (Modified from Bulwer BE, Sherman SK, Thomas J: *Physics of echocardiography*. In Savage RM, Aronson S, Sherman SK [eds]: *Comprehensive Textbook of Perioperative Transesophageal Echocardiography*. Philadelphia, Wolters Kluwer: Lippincott, Williams & Wilkins, 2009, p 23.)

“hollowed-out” waveform, indicative of the narrow range or spectrum of flow velocities present within the sample. In a Doppler assessment of the left ventricular (LV) outflow tract (LVOT), for example, the Doppler profile represents the velocity of blood flow throughout systole. If this flow is primarily laminar, blood flow velocities within the sample region will be relatively uniform at each instant during the cardiac cycle. If the flow becomes turbulent, with blood moving at different velocities or in multiple directions, the spectrum of velocities will be wider.

As illustrated by the Doppler equation (see earlier), the velocity of blood flow determined from the Doppler shift will change as the angle of insonation changes. Practically, this means that if the vector of flow is not directly in line with the ultrasound beam, the velocities calculated by the Doppler shift will be underestimated. This problem can be corrected by applying an angle adjustment at the machine level, although the further the angle of flow deviates from the angle of the beam, the greater the likelihood for error in the calculation, and in general it is best to avoid Doppler assessments that are substantially off-angle.

Doppler Echocardiography in Practice

Doppler echocardiography is used primarily to assess blood flow velocity in the heart and blood vessels. Within the heart the velocity of blood flow is itself dependent on the pressure gradient between cardiac chambers, with higher gradients resulting in higher velocities. Knowledge of the velocity of blood flow between two chambers, for example, can be used to infer the pressure gradient between them. This relationship can be described by the Bernoulli equation, which estimates the pressure gradient between two chambers separated by an orifice based on the velocity of flow through the orifice:

$$P_1 - P_2 = \frac{1}{2}\rho(V_2^2 - V_1^2) + \rho \int_1^2 \frac{dv}{dt} ds + R(\vec{v})$$

Convective Acceleration Flow Acceleration Viscous Friction

where P_1 and P_2 are the pressures proximal and distal to the orifice and V_1 and V_2 are the velocities proximal and distal to the orifice. In practice, a simplified form of the Bernoulli equation that ignores flow acceleration and viscous friction can be used:

$$P_1 - P_2 = \frac{1}{2}\rho(V_2^2 - V_1^2)$$

The equation can be even further simplified because velocities proximal to an orifice or stenosis are generally quite low in comparison to those distal to the orifice and can usually be ignored, which leaves

$$P_1 - P_2 = 4V^2$$

For example, the blood flow velocity of tricuspid regurgitation (TR) can be used to calculate the pressure gradient between the right ventricle and the right atrium, which when added to an estimate of right atrial (RA) pressure, provides an estimate of pulmonary artery systolic pressure. Similarly, the highest blood flow velocity between the left ventricle and the aorta in a patient with aortic stenosis can be used to calculate the peak instantaneous pressure gradient across the aortic valve. It is important to appreciate that Doppler

FIGURE 14-8 Volumetric flow assessments using spectral Doppler. The volume of a cylinder is CSA multiplied by length. Using this geometric assumption and assuming constant flow during the cardiac cycle, SV can then be derived from the CSA of the LVOT measured on the parasternal long-axis view. This is then multiplied by the VTI measured on apical views of the transthoracic examination. Ao = aorta; LA = left atrium; LV = left ventricle.

echocardiography measures *velocity*, neither pressure nor flow directly. Pressure gradients can be inferred from velocities based on the Bernoulli equation, but absolute pressure within chambers cannot be directly measured as in cardiac catheterization. Similarly, volumetric flow cannot be measured directly, although there are Doppler-based methods that permit estimation of flow relatively precisely.

Assessment of Flow and Continuity Equation

Even though Doppler methods are used to assess blood flow velocities, the magnitude of flow can be inferred by multiplying the velocity-time integral (VTI; i.e., integrated velocity throughout the cardiac cycle) by the cross-sectional area (CSA) of the region being interrogated (Fig. 14-8). For example, stroke volume (SV) can be estimated by interrogating the LVOT region with PW Doppler and multiplying the VTI by the CSA (which is calculated by measuring the diameter):

$$SV = VTI_{LVOT} \times Area_{LVOT}$$

The continuity principle, which is based on conservation of mass and states that flow in one region of the heart should be equivalent to flow in another region (assuming no intervening shunt), can be used to determine an unknown CSA, such as that of a stenotic valve. The CSA of a stenotic valve can be difficult to measure directly (i.e., by planimetry); by estimating the flow proximal to the valve and the VTI through the valve, valve area can be determined. Even though velocities through stenotic valves can be too high to assess with PW Doppler, CW Doppler can be used, assuming that the highest attained velocities correspond to the narrowest region along the Doppler path being interrogated. Because the continuity principle states that flow through the LVOT must equal flow through the aortic valve (AV),

$$VTI_{LVOT} \times Area_{LVOT} = VTI_{AV} \times Area_{AV}$$

solving for $Area_{AV}$ yields an estimate of the desired valve area. The accuracy of this estimate depends on the accuracy of the known CSA measurement and optimal positioning of the PW Doppler cursor.

THE STANDARD ADULT TRANSTHORACIC ECHOCARDIOGRAPHIC EXAMINATION

The standard adult TTE examination consists of a combination of two-dimensional, M-mode, and Doppler imaging. The recommended

comprehensive examination protocol involves optimal image acquisition of echocardiographic views, each of which is described in terms of three principal components: (1) the standard transducer position or “windows,” (2) the orthogonal echocardiographic imaging planes, and (3) the anatomic region of interest (Figs. 14-9 and 14-10). At each transducer position the operator optimally acquires two-dimensional images with color flow Doppler, spectral Doppler, or M-mode images as indicated.

M-Mode Echocardiography

M-mode echocardiography (see Fig. 14-1) provides greater temporal resolution than does standard two-dimensional imaging and remains the method of choice for certain linear measurements, particularly those that are collinear with the ultrasound beam, such as measurement of septal and posterior wall thickness and LV chamber dimensions on parasternal views. Because M-mode echocardiography is essentially a one-dimensional imaging technique, this method has several important limitations that should be recognized, especially when M-mode–derived data are used to determine information about cardiac size and shape. In particular, M-mode–based estimates of LV volume, mass, and function can be inaccurate in patients with LV geometries that deviate substantially from normal, such as following myocardial infarction (MI). M-mode can also be combined with color flow Doppler (color M-mode) to provide accurate timing-related information about flow and has been used for assessment of diastolic function (see later).

Imaging Artifacts

Ultrasound imaging artifacts are ubiquitous in echocardiography and in large measure are products of the physical principles of ultrasound. Artifacts can include the appearance of structures that do not exist or can be the result of structures that do exist, such as ribs obscuring proper visualization of existing structures. Although imaging artifacts can result from faulty ultrasound equipment, interference from other electronic equipment, or improper ultrasound machine settings, most artifacts are due to physical interactions between ultrasound and tissue. Several types of artifacts are common (Fig. 14-11), including (1) attenuation artifacts, which result in “shadowing” typically caused by ribs or bony structures; (2) reverberation artifacts, which are caused by internal reflections; (3) side lobe artifacts, which occur when structures reflected from “side lobes” of the ultrasound beam are erroneously mapped onto the image; and (4) rib “dropout” artifacts, in which cardiac structures are obscured because of the marked ultrasound attenuation caused by the bony rib cage. One type of artifact, the comet-tail artifact, can be useful diagnostically to detect interstitial fluid in the lungs.

Assessment of Cardiac Structure and Function

The primary goal of the echocardiographic examination remains assessment of cardiac structure and function. Each chamber and valve can be assessed qualitatively and quantitatively by experienced operators to define any alterations in cardiac size and geometry by using comprehensive measurements. Established normal values are shown in Tables 14-1 through 14-5. Measurements of cardiac structures are typically made in various locations throughout the heart, and linear, area, or volumetric measures can be obtained. These methods are often complementary to one another; for example, although volumetric measurements of the left ventricle (see later) are generally considered best suited to characterize LV size, many laboratories continue to record linear cavity measurements, a practice that is supported by the extensive literature correlating these measures with outcomes in numerous disease states. Moreover, linear measures can be subject to less variability than area- or volume-based measures and can therefore be more reliable when assessing changes over time.

FIGURE 14-9 Standard adult transthoracic echocardiography imaging planes and examination protocol and nomenclature recommended by the ASE. Each echocardiographic view uses three parameters to describe each view as demonstrated above. See Figure 14-10 for exposition of the abbreviations used. (Modified from Bulwer BE, Shernan SK, Thomas JD: *Physics of echocardiography*. In Savage RM, Aronson S, Shernan SK [eds]: *Comprehensive Textbook of Perioperative Transesophageal Echocardiography*. Philadelphia, Wolters Kluwer: Lippincott, Williams & Wilkins, 2009, pp 1-41.)

FIGURE 14-10 Labeled still frames of standard adult TTE views. Compare with Figure 14-9. Ao = aorta; LA = left atrium; RA = right atrium.

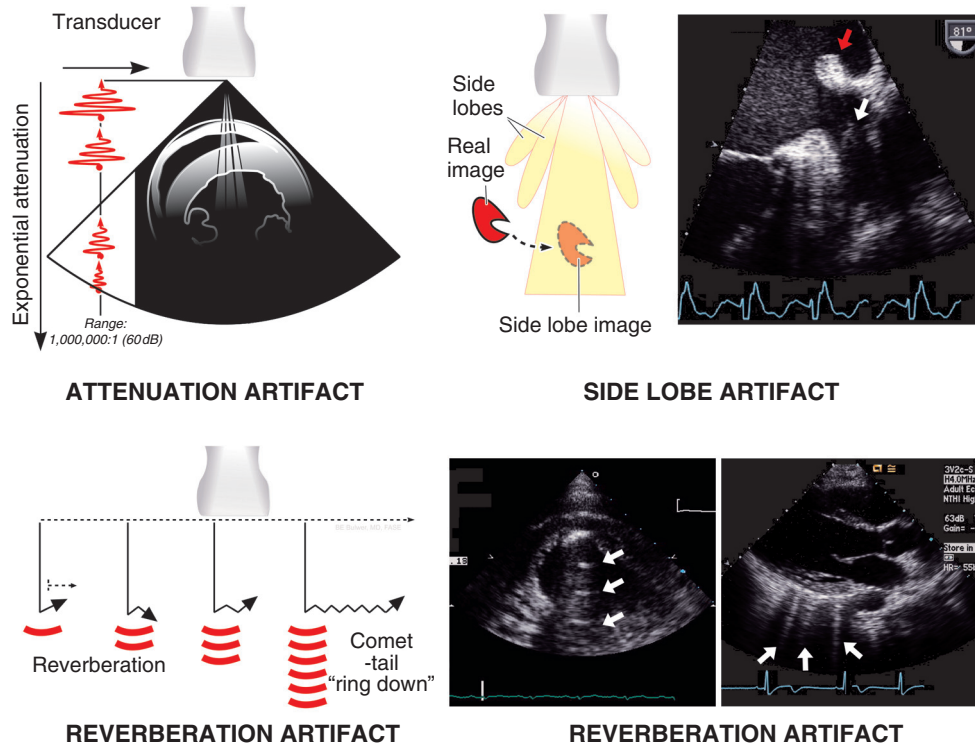

FIGURE 14-11 Common imaging artifacts seen in echocardiography. Attenuation artifacts, a result of the invariable diminution in ultrasound beam intensity with increasing depth, results in attenuation and dropout artifacts (**upper left**). Side lobe artifacts occur when structures in the path of the side lobe beams are erroneously mapped into the image (**upper right**). Reverberation artifacts are common (**lower panels**). They may be large, as in the case of reflections from the inflow tube of an LVAD (three parallel arrows, below center), or appear as fine comet-tail or “ring-down” artifacts because of multiple reverberations that invariably occur at the highly specular epicardial-pleural interface (**lower right**).

Left Ventricular Structure: Size and Mass

LV volumes can be estimated from one of several formulas that use either linear or two-dimensional measurements to calculate a volume based on the assumption that the left ventricle approximates a prolate ellipsoid (**Fig. 14-12**). These approaches are limited when ventricular geometry deviates substantially from normal, as is the case in patients with MI, in whom the ventricle can be substantially distorted. The single-plane or biplane Simpson method of discs is an approach that does not rely on such rigid geometric assumptions and has been demonstrated to be the most accurate method (**Fig. 14-13**). This method requires manually identifying the endocardial border in the apical four- and/or two-chamber views with computerized assistance to measure the diameter of equally distributed slices along the ventricle. A CSA is calculated from this diameter by assuming a circle if the single-plane method is used or an ellipse if two orthogonal planes are used. Even though the Simpson method is usually more accurate than other methods of assessing ventricular volumes, precise identification of the endocardial border can be challenging when image quality is reduced. Moreover, foreshortening of the ventricle in one of the apical views, which can occur simply by minor changes in the transducer angle, can dramatically reduce the measured volume and adversely affect volumetric estimations. Three-dimensional echocardiography has the potential to reduce some of the inherent limitations of two-dimensional imaging (see Three-Dimensional Imaging, later).

FIGURE 14-12 Geometric models and assumptions used in quantification of volumes of the left ventricle (LV) in two-dimensional echocardiography. (Modified from Bulwer BE, Rivero J, Solomon SD: *Basic principles of echocardiography and tomographic anatomy*. In Solomon SD [ed]: *Atlas of Echocardiography*. 2nd ed. Philadelphia, Current Science/Springer Science, 2009, pp 1-24.)

Philadelphia, Current Science/Springer Science, 2009, pp 1-24.)

LV mass may be calculated by using one of several formulas that take into account both wall thickness and chamber size² (Fig. 14-14; see Table 14-1). These formulas have been validated in geometrically normal ventricles, but their accuracy is markedly reduced in the setting of altered ventricular geometry, such as following MI. LV hypertrophy is defined by the overall LV mass. In general, if LV diameter is not decreased, wall thickness of 12 mm or greater is usually indicative of LV hypertrophy (see Table 14-1). Both myocardial and valvular diseases can result in remodeling of the left ventricle and hence abnormal ventricular geometry. Categorization of ventricular geometry is based on relative wall thickness and the LV mass index (Fig. e14-2). The specific pattern of ventricular remodeling has been related to prognosis in a variety of diseases.²

Left Ventricular Systolic Function

Echocardiography offers several methods for assessment of systolic function. The LV ejection fraction (LVEF), calculated as the difference between end-diastolic volume and end-systolic volume divided by end-diastolic volume, remains the most commonly used method for assessing systolic function. It is one of the best-studied measures in cardiovascular medicine and has proved useful in diagnosis and risk stratification in a variety of cardiovascular diseases. Although accurate assessment of LVEF requires calculation from ventricular volumes, many echocardiography laboratories estimate LVEF visually. Even though calculation of LVEF from volumes is preferred, the accuracy of this estimation is affected by image quality, endocardial border definition, ventricular geometry, and representative orthogonal imaging planes. When one or more of the aforementioned factors are suboptimal, visual estimation by experienced echocardiographers can be more accurate and sufficient for most clinical scenarios.

Other approaches are commonly used in addition to LVEF to assess systolic function. SV can be determined by subtracting end-systolic volume from end-diastolic volume (calculated as described earlier) or through Doppler methods. Multiplying the VTI in the LVOT, assessed with PW Doppler on the apical four-chamber view, by the cross-sectional diameter at the same location (measured on the parasternal long-axis view) yields SV (see Fig. 14-8), which can be multiplied by the heart rate to obtain cardiac output.

Several other novel methods have been proposed for assessment of systolic function. The myocardial performance index, also known as the Tei index, is defined as the sum of isovolumic relaxation time and isovolumic contraction time divided by ejection time, and this

method takes into account both systolic and diastolic performance, with a lower index being associated with better function.² In adults, values of the LV index lower than 0.40 and RV index lower than 0.30 are considered normal. This measure has been related to outcomes in a variety of conditions, including heart failure and following MI. Doppler tissue imaging (DTI) can be used to assess myocardial contraction velocity, or S' , although this technique has proved more useful for assessment of diastolic function (see [Doppler Tissue Imaging](#) later).

Myocardial Strain Imaging

Myocardial deformation, or strain, imaging is a relatively novel yet promising method for assessment of cardiac function. Strain refers to the percent deformation between two regions and reflects shortening in myocardial muscle.³ Myocardial strain can be assessed by Doppler methods in which myocardial tissue velocities in multiple regions are integrated to obtain change in distance. Doppler-based assessments of myocardial strain are relatively noisy and require dedicated acquisition during scanning, thus limiting their usefulness. In addition, Doppler-derived strain information is angle dependent. In contrast, strain imaging based on speckle-tracking techniques has proved to be much more robust and reliable, although it has poorer temporal resolution than Doppler-based techniques do, thus limiting its use at

high heart rates. Nevertheless, two-dimensional methods have virtually replaced Doppler-based strain assessments for most applications. These techniques take advantage of the coherent speckle within the myocardial tissue signature to determine regions that are contracting versus those that are moving passively (Figs. 14-15 and e14-3). Myocardial strain measures have been validated with sonomicrometry,⁴ and strain can be estimated in the longitudinal, circumferential,

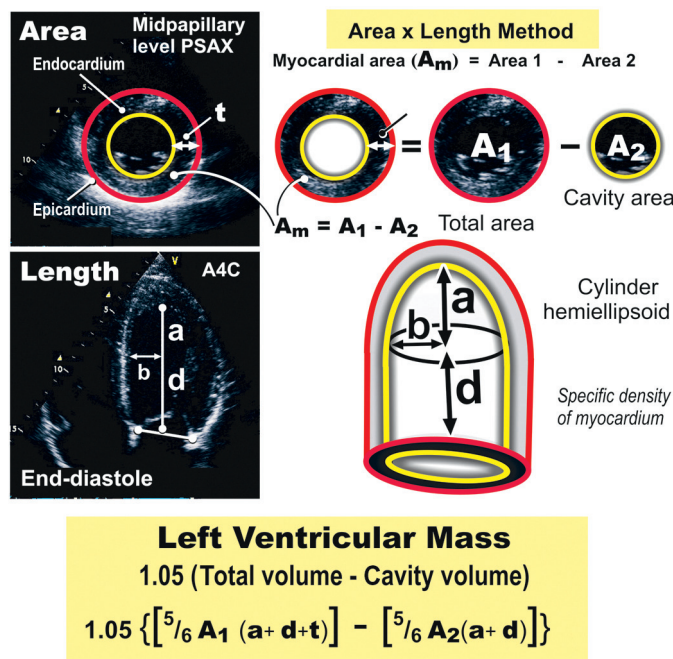

FIGURE 14-14 LV mass calculation in two-dimensional echocardiography using an area-length method for a cylinder hemiellipsoid. Area 1 (A_1) is the total planimetered area at the mid-LV level on the parasternal short-axis (PSAX) view; area 2 (A_2) is the planimetered LV cavity area; A_m is the myocardial "shell" area; b = minor axis radius; t = wall thickness. (Modified from Bulwer BE, Rivero J, Solomon SD: *Basic principles of echocardiography and tomographic anatomy*. In Solomon SD [ed]: *Atlas of Echocardiography*. 2nd ed. Philadelphia, Current Science/Springer Science, 2009, pp 1-24.)

FIGURE e14-2 Classification of ventricular geometry based on relative wall thickness and LV mass index.

FIGURE e14-3 Two-dimensional (2D) speckle tracking methodology. Speckles are inhomogeneous interference patterns that result from the interaction of ultrasound with the myocardium. Each area of myocardium, with its unique signature speckle, can be tracked during the myocardial deformation cycle. Unlike Doppler-based deformation imaging measures, speckle tracking-derived deformation measures are angle independent. A4C = apical four-chamber view.

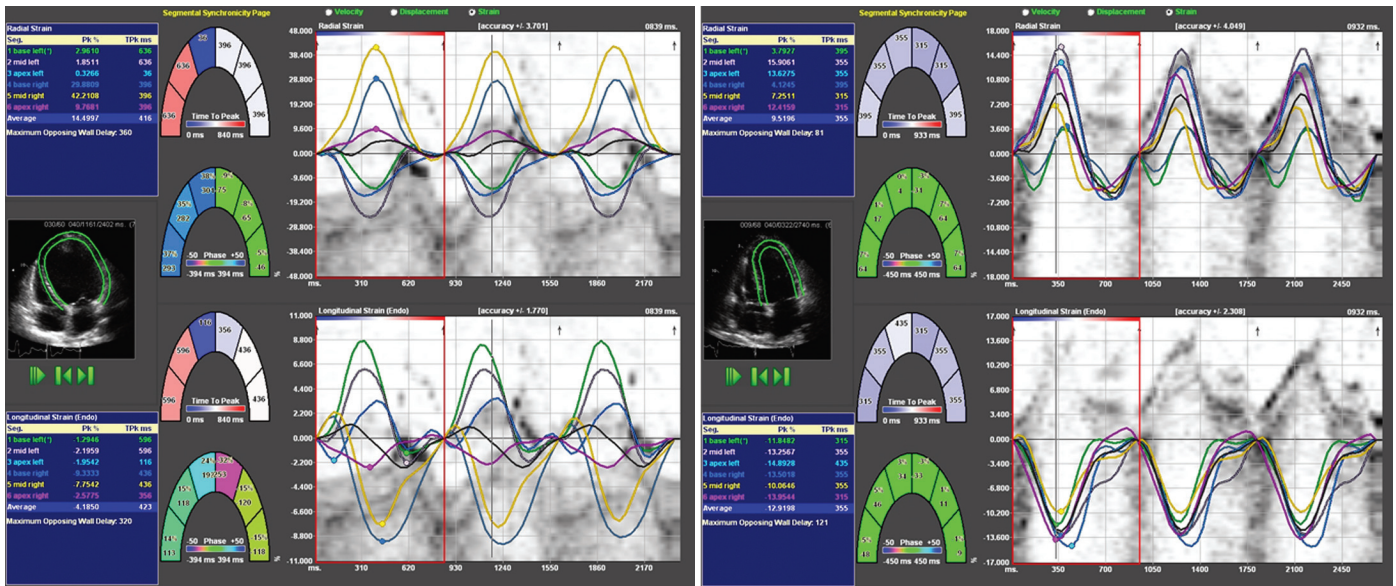

FIGURE 14-15 Assessment of myocardial strain from the apical four-chamber view. Average radial and longitudinal strain is calculated from six different regions in the ventricle. The waveforms depicted demonstrate both the timing and magnitude of peak strain in these regions. The **left panel** shows a patient with cardiomyopathy before therapy with a cardiac resynchronization device. The **right panel** shows same patient after 12 months of CRT with dramatic improvement in ventricular synchrony.

and radial directions by using the appropriate imaging plane (see Fig. 14-15). Speckle methods can also be used to assess ventricular twist and torsion, or the wringing motion of the heart during contraction and relaxation.

Longitudinal strain can be assessed with the apical four-chamber view, and global longitudinal strain has emerged as an important measure of cardiac performance that has been shown to add incremental value to standard measures such as the ejection fraction. Current equipment both assesses regional strain and calculates global longitudinal strain either by averaging regional strain or by determining the percent difference in the endocardial perimeter between systole and diastole. Longitudinal deformation reflects function of the subendocardial myocardial fiber bands primarily, whereas circumferential deformation, best assessed on short-axis views, may reflect the function of more epicardial layers (see Fig. 14-15).

Several diseases have been associated with a reduction in global longitudinal myocardial function as estimated by strain, including hypertension, diabetes mellitus, renal insufficiency, infiltrative cardiomyopathies, valvular heart disease, and hypertrophic cardiomyopathy (HCM).⁵ These measures also appear to predict survival or the development of heart failure in patients following MI and correlate with the burden of scar.

Myocardial deformation imaging has been used recently for the evaluation of cardiac synchrony by assessing the time to peak strain (reflective of maximal contraction) across many cardiac regions. Both regional timing, reflecting synchrony, and myocardial peak strain, reflecting contractile function, have prognostic significance in patients undergoing cardiac resynchronization therapy (CRT) (see Chapters 26 and 36), and these data have been used to identify those who will benefit most from CRT.⁶⁻⁸

In addition to assessment of global function, strain imaging can be used to assess and quantify regional function. Regional strain has been shown to correlate with the degree of myocardial scar in patients with ischemic heart disease (see Chapter 17) and in HCM (see Chapter 66).⁹⁻¹¹ These measures can also be used to assess ischemia in the setting of stress echocardiography. An offshoot of myocardial strain imaging has been the quantitative assessment of ventricular twist and torsion (Fig. 14-16). There are several limitations of strain imaging based on two-dimensional echocardiography. First, myocardial deformation occurs in three dimensions and out-of-plane movement is lost. Second, these measures are subject to the same limitations as conventional ultrasound images, including frame rate and image quality. Finally, although deformation imaging is offered by most ultrasound vendors, as well as by several off-line systems, there is a lack of standardization in technique, data acquisition, and normal values among vendors. As strain imaging measures become

standardized and these techniques become more refined and automated, their usefulness and applicability will increase.

Left Ventricular Regional Function

Even though measures of global LV function provide quantification of overall cardiac performance and have prognostic value, regional function can vary substantially, such as in ischemic heart disease or other focal processes. Acute MI can cause regional wall motion abnormalities in a coronary distribution, with very specific myocardial regions being associated with specific coronary artery distributions (see **Myocardial Infarction**, later). Regional wall motion may be assessed qualitatively or semiquantitatively with a scoring system (Fig. e14-4). The most popular current scoring system is based on a 17-segment model advocated by the American Society of Echocardiography (ASE) in which each segment is scored as normal (1 point), hypokinetic (2 points), akinetic (3 points), or dyskinetic (4 points). The wall motion score index (WMSI) is equal to the sum of these grades divided by the number of segments visualized, so a normokinetic ventricle should have a score of 1.0. A WMSI of 1.7 or higher is usually associated with the physical examination findings of heart failure. This score also has prognostic value, and a higher score is an independent predictor of mortality and morbidity, including increased hospitalization for heart failure, following MI.

The main goal of detecting regional myocardial dysfunction is to identify patients with coronary artery disease (CAD). Nevertheless, assessment of regional wall motion cannot easily distinguish between old and new wall motion abnormalities, although local myocardial thinning and increased brightness consistent with substantial scar tissue can be suggestive of chronic infarction. Typically, MI is associated with discrete regions of severe hypokinesis, akinesis, or even dyskinesis with a discernible "border" or hinge point. Regional wall motion abnormality can be apparent even within the first few minutes of acute MI, thus making assessment of regional wall motion particularly suited for diagnosis in the acute setting, for example, in patients with acute chest pain and equivocal abnormalities on the electrocardiogram (ECG) in whom a discrete regional wall motion abnormality might argue for early intervention (see Chapters 51 and 52). Although MI, either acute or old, is the most likely reason for regional wall motion abnormalities, other conditions such as myocarditis or sarcoidosis can affect the myocardium regionally, but not generally in a clear coronary distribution. Additionally, the LV dysfunction that

FIGURE e14-4 WMSI for assessment of regional ventricular function. See Figure 14-29 for coronary distributions.

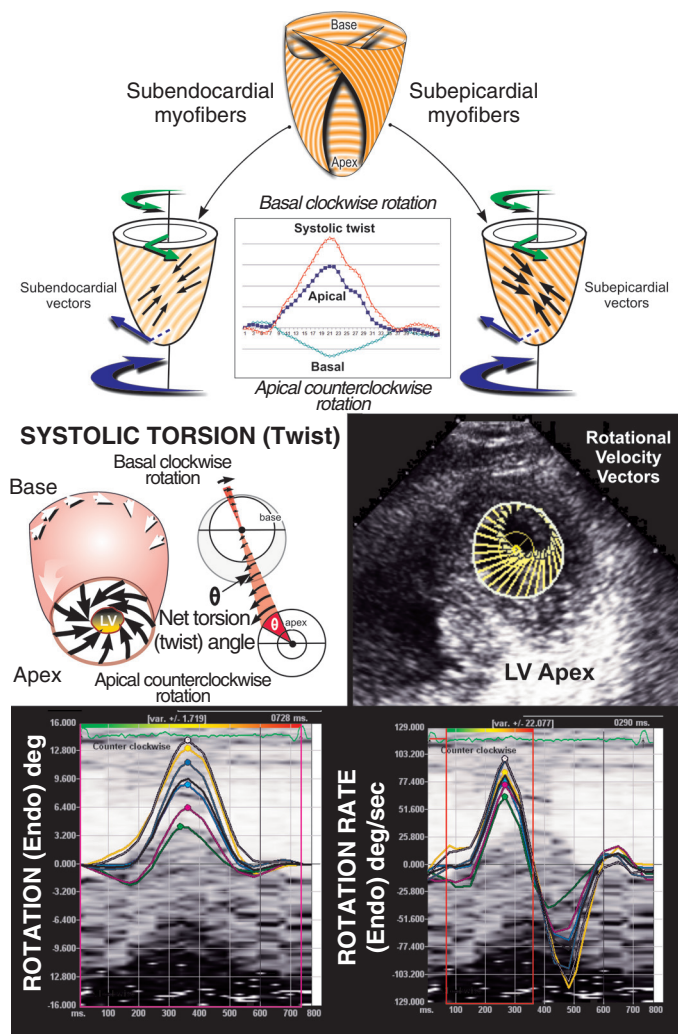

FIGURE 14-16 Ventricular torsion (or twist) can be assessed by comparing the rotation occurring at the base of the heart with that occurring at the apex. Rotation at two locations can be assessed by speckle tracking echocardiography. Rotation and the rate of rotation can be assessed and displayed. (Modified from Bulwer BE, Solomon SD: Assessment of systolic function. In Solomon SD [ed]: *Atlas of Echocardiography*. 2nd ed. Philadelphia, Current Science/Springer Science, 2009, p 63.)

can accompany valvular or hypertensive heart disease may also be regionally variable.

Assessment of regional wall motion is particularly important in stress echocardiography, in which induced regional wall motion abnormalities in the setting of exercise-induced or pharmacologic stress indicate myocardial ischemia. In stress echocardiography, regions are compared before and after stress in a side-by-side fashion, and wall segments with unchanged or worsening systolic function are compared qualitatively and scored (see [Stress Echocardiography](#)).

Left Ventricular Diastolic Function

Noninvasive assessment of diastolic function has remained one of the more challenging aspects of echocardiography. The “gold standard” for assessment of diastolic function has been the invasively obtained pressure-volume loop in which diastolic function is assessed as the instantaneous relationship between pressure and volume. Diastolic dysfunction is extremely prevalent in patients with hypertension and in older adults and is thought to contribute substantially to the pathophysiology of heart failure with preserved ejection fraction (HFpEF) (see [Chapter 27](#)). Doppler echocardiography is best suited to assessment of diastolic function because of its high temporal resolution, and several Doppler-based methods can be used to

assess various measures of cardiac performance during diastole ([Table 14-6](#)).

Mitral Inflow Patterns

Mitral inflow Doppler can be used to assess flow from the left atrium to the left ventricle during the early and late phases of diastole ([Fig. 14-5](#)). The transmitral inflow velocity at a given point in time is a reflection of the pressure gradient between the chambers. The E wave occurs during early diastole when the ventricle is filling passively. The A wave represents the velocity of blood flow during late diastole and atrial contraction. Traditional classification of diastolic function has been based on the pattern (i.e., relative heights) of the E and A waves. E wave velocity is dependent on the transmitral pressure gradient and is thus directly related to left atrial (LA) pressure and inversely related to ventricular compliance. The height of the A wave is additionally dependent on the strength of atrial contraction. Normally in individuals younger than 65 years, E wave height is greater than A wave height, with typical ratios of between 1.2 and 1.5 (see [Table 14-6](#)). As diastolic function worsens and with aging, the E wave generally declines as ventricular compliance worsens, as long as LA pressure has not increased. Simultaneously, the A wave typically increases as atrial contraction strengthens to compensate for the reduced ventricular compliance. Moreover, the deceleration time of the E wave increases as compliance worsens initially. However, as diastolic function continues to worsen, the E wave increases as LA pressure rises, and the relative height of the A wave declines as ventricular pressure rises and atrial function begins to worsen, so the E/A ratio may revert to relatively normal (termed pseudonormalization). Because pseudonormal patterns can appear similar to normal patterns, these measures alone can be misleading. Further worsening of diastolic function leads to the so-called restrictive pattern in which the descending slope of the E wave becomes very steep because of abrupt cessation of mitral inflow ([Fig. 14-17](#)), as indicated by a rapid E wave deceleration time. Thus both the pattern of the E and the A waves and mitral deceleration time follow a biphasic course as diastolic function worsens, which limits the usefulness of these measures alone in assessment of diastolic function.

Pulmonary Venous Doppler Flow Patterns

Pulmonary flow patterns can also be useful in the assessment of diastolic function, especially if considered complementary to mitral inflow Doppler patterns. Pulmonary vein flow has three components: (1) the S wave, which consists of forward flow from the pulmonary veins to the left atrium during ventricular systole; (2) the D wave, which consists of passive diastolic flow during ventricular diastole; and (3) the AR wave, which indicates flow reversal into the pulmonary veins during atrial contraction ([Fig. 14-18](#)). Patients with impaired LV relaxation will demonstrate blunting of the S wave such that it is substantially lower than the D wave. Reduced LV compliance may also result in greater flow into the pulmonary veins during atrial contraction.

Doppler Tissue Imaging. DTI applies Doppler imaging principles to the assessment of myocardial contraction and relaxation. Standard Doppler uses filters that focus on ascertainment of the high-frequency, low-amplitude signals that arise from rapidly moving red blood cells. In contrast, DTI uses filters that optimize assessment of the higher-amplitude, low-velocity signals that arise from myocardial motion. Because DTI is based on standard Doppler techniques, it is subject to the same limitations, including angle dependence.¹² Aliasing is not a practical consideration because tissue velocity tends to be at least an order of magnitude lower than blood flow velocity.

DTI is ideally suited to assessment of diastole because of its very high temporal resolution and ability to quantify myocardial wall motion velocity directly, which itself is dependent on the rates of myocardial contraction and relaxation. Even though DTI can be used to assess myocardial velocity during relaxation and contraction at any location in the heart, assessment of myocardial motion is generally performed by sampling the velocity of mitral annular motion. The mitral annulus moves longitudinally toward the apex, which remains relatively fixed, in systole and away from the apex during diastole. Either the medial or the lateral mitral annulus can be sampled (although

their velocities differ), and the Doppler waveforms produced reflect systolic contraction (S'), early diastolic relaxation (E'), and late diastolic relaxation velocities (A'). Early mitral relaxation velocity, or E', represents the rate of myocardial relaxation during early diastole and is inversely related to tau, the time constant of ventricular relaxation. E' velocity ranges from greater than 20 cm/sec in children and young adults to less than 5 cm/sec in patients with severe diastolic dysfunction (e.g., amyloidosis). This measure is extremely age dependent; it declines rapidly in early adulthood and continues to decline with aging.

Dividing E' into the standard mitral E wave velocity (E/E') yields a measure that has been correlated with filling pressure. Because E velocity reflects the atrial-to-ventricular pressure gradient, it is dependent on both LA pressure and LV compliance. Because E' is itself a measure of LV compliance, dividing E by E' yields a measure that reflects LA pressure, which itself is dependent on LV end-diastolic pressure. Although these measures have been shown in some laboratories to correlate with LV filling pressure, they may be insensitive to changes in filling pressure and may not be suitable for monitoring patients during therapy.¹³

A number of other methods have also been used for assessment of diastolic function. The isovolumic relaxation time (IVRT) represents the period between closure of the aortic valve and the start of ventricular filling. Prolongation of the IVRT is associated with abnormal relaxation, although shortening of the IVRT can occur in patients with restrictive LV filling. Mitral, or E wave, deceleration time is a measure of the time from peak mitral inflow to cessation of mitral inflow. In patients with severe restrictive physiology, the mitral deceleration time

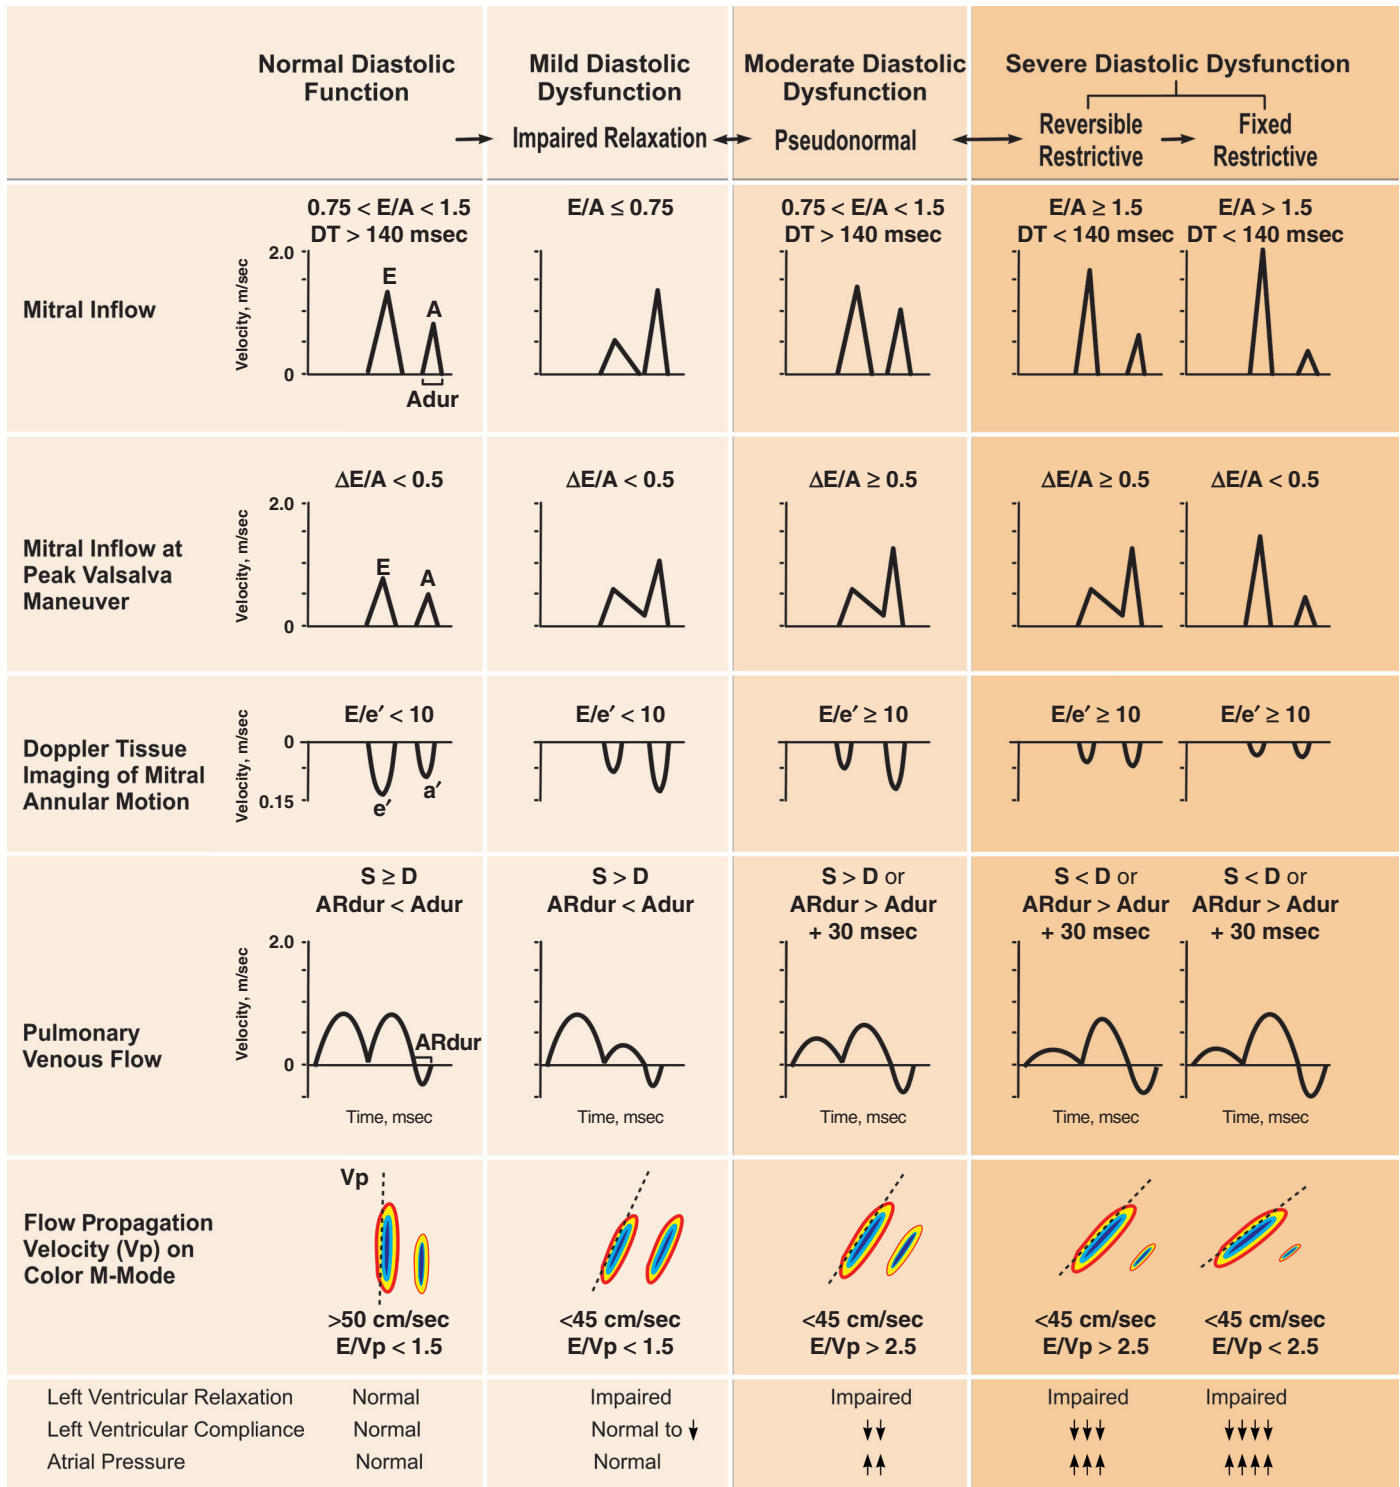

FIGURE 14-18 Diastolic function classification scheme. JAMA 289:194, 2003.)

will be extremely rapid, less than 140 milliseconds, and this finding has been associated with adverse prognosis in patients with heart failure and following MI.¹³ This is most often encountered in patients with both systolic and diastolic dysfunction and is generally considered a sign of severe diastolic dysfunction. In earlier phases of diastolic dysfunction, deceleration time can actually increase, hence making interpretation of this measure difficult.

Color M-Mode and Flow Propagation

Color M-mode can be used to assess transmitral flow propagation velocity (Vp). The M-mode function is initiated while obtaining color flow Doppler through the mitral valve, and the color flow information is superimposed on the M-mode image (Fig. 14-19). The slope of the E wave flow represents flow propagation, which itself is inversely

related to tau, the time constant of relaxation. Patients with abnormalities in ventricular relaxation will have reduced acceleration of blood flow, and this slope will be less steep. In practice, these measures can be difficult to obtain.

Assessing Diastolic Function in Clinical Practice

In clinical practice, assessment of diastolic function requires synthesizing information from multiple assessments, including mitral inflow Doppler patterns, tissue Doppler, and pulmonary venous patterns. Several schemes have been developed to grade diastolic function based on these parameters (see Fig. 14-18). Although these schemes allow “grading” of diastolic function, data on the relationship between these grades and clinical outcomes remain limited, and abnormalities in diastolic function are extremely common in patients with hypertension and in older adults.¹⁵ Moreover, abnormalities in diastole are not necessarily associated with clinical symptoms or overt heart failure. Assessment of diastolic function during exercise, termed the “diastolic stress test,” may help unmask abnormalities in diastolic function that contribute to symptoms only during exertion.¹⁶

Right Ventricular Structure and Function

Assessment of the right ventricle has proved especially challenging for two-dimensional echocardiography. Even though the left ventricle

is relatively easily characterized as a prolate ellipsoid, the odd crescentic shape of the right ventricle makes modeling of volumes considerably more complex (Fig. e14-6). Moreover, because visualization of the entire right ventricle is not encompassed by any single two-dimensional echocardiographic view, multiple measurements from multiple views are necessary to fully assess this chamber. The normal right ventricle is accustomed to low pulmonary vascular resistance (PVR) and is thus extremely sensitive to changes in afterload. Conditions that increase PVR acutely, such as pulmonary embolism (see Chapter 73), will cause marked RV dilation and dysfunction. Conditions that increase PVR more chronically will lead to RV hypertrophy and dilation, but RV function is usually maintained until the late stages of disease (see Chapter 74).

Several methods are commonly used to assess RV function (Table 14-7). RV fractional area change (FAC) (Fig. 14-20) can be used in lieu of a volumetric method for calculating the RV ejection fraction and is easily determined by calculating the RV area in diastole (RVAd) and systole (RVAs) on the apical four-chamber view:

$$\text{FAC} = (\text{RVAd} - \text{RVAs}) / \text{RVAd}$$

This method is relatively unaffected by off-axis measures because they will affect systolic and diastolic areas similarly, yet it is still

FIGURE 14-19 Transmittal flow propagation demonstrated by color M-mode. Flow propagation velocity is assessed as the slope of the mitral inflow pattern, which will be more shallow when velocity is impaired. This measure has been shown to be inversely related to tau, the time constant of relaxation. bpm = beats/min; HR = heart rate; Vp = transmittal flow propagation velocity.

dependent on adequate definition of the RV free wall endocardium. Assessment of RV function by FAC has been shown to provide incremental prognostic value in patients with heart failure and following MI.¹⁷ Several other methods have proven useful for assessment of RV function. Tricuspid annular plane systolic excursion (TAPSE) is a measure of the excursion of the tricuspid annulus and is most commonly measured with M-mode imaging (Fig. 14-21). The motion of the tricuspid annulus can similarly be assessed with DTI, and TAS' may be simpler to measure and more robust than TAPSE (Fig. 14-22). RV regional function may have particular importance in conditions in which RV afterload increases abruptly, such as pulmonary embolism (see **Pulmonary Embolism**, later), in which regional RV function may be preserved in the apical and basal free wall segments but dyskinetic or akinetic in the midregion.

Left and Right Atria

LA enlargement has been associated with adverse cardiovascular outcomes. The left atrium enlarges under several pathologic conditions, including LV systolic and diastolic dysfunction and atrial fibrillation. LA size is thought to reflect LV filling pressure and has been considered an integrator of diastolic function over time. Several methods can be used to quantify LA size. A linear measurement of the left atrium is usually obtained on the parasternal view. LA area can be assessed from the apical views and volume calculated by applying the Simpson biplane methods to the apical four- and two-chamber views. Volumes should be normalized to body size, either

by indexing to body surface area or height to the 2.7 power (see Table 14-4).

The function of the left atrium throughout the cardiac cycle can also be assessed. LA function contributes to overall cardiac performance and itself is affected by LV compliance. There are several phases of LA function: the reservoir phase in which the atrium fills rapidly from the pulmonary veins during early LV systole; the conduit phase during which LA blood empties into the left ventricle during early ventricular diastole; and the contractile, or pump, phase in which the atrium augments LV filling in late diastole. Both the active and passive emptying volumes of the left atrium can be assessed. LA passive emptying volume is defined as the maximum LA volume

minus the LA volume before atrial contraction. LA active emptying volume is defined as the LA volume before atrial contraction minus the minimum LA volume (following LA contraction).

Assessment of the right atrium is best performed from the subcostal or apical views. RA size is a reflection of right-sided filling pressure. Indexed RA volumes based on volumetric assessment are similar to LA volumes in healthy men and slightly smaller in healthy women. Assessment of both the right atrium and inferior vena cava (IVC) is important in the estimation of RA pressure, which is essential for calculating pulmonary artery systolic pressure from tricuspid regurgitant velocity. Qualitative evidence of elevated RA pressure includes a dilated right atrium, dilation of the IVC, or attenuation of IVC collapse during inspiration. Several methods have been used to estimate RA pressure by echocardiography, but most involve a combination of IVC size and the amount that the IVC collapses with inspiration. A rough scale of RA pressure has been developed that combines assessment of IVC size and respirophasic collapse (Table 14-8): complete (>50%) collapse, RA pressure = 0 to 5 mm Hg; partial collapse, RA pressure = 5 to 10 mm Hg; and no (<50%) collapse, RA pressure = 15 mm Hg.¹⁸

TRANSESOPHAGEAL ECHOCARDIOGRAPHY

TEE is an alternative method to obtain ultrasound images of the heart in which a smaller ultrasound transducer is introduced into the

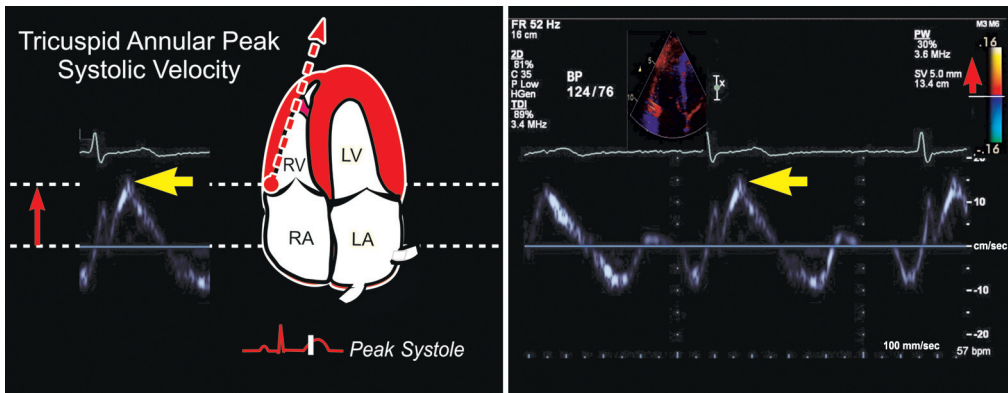

FIGURE 14-22 Tissue Doppler method used to derive peak systolic velocity (arrow) measured at the tricuspid annulus on an apical four-chamber view of the right ventricle. BP = blood pressure; LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

TABLE 14-8 Estimation of Right Atrial Pressure on the Basis of Inferior Vena Cava Diameter and Collapse

VARIABLE	NORMAL (0-5 [3] mm Hg)	INTERMEDIATE (5-10 [8] mm Hg)		HIGH (15 mm Hg)
IVC diameter	≤2.1 cm	≤2.1 cm	>2.1 cm	>2.1 cm
Collapse with nasal inhalation	>50%	<50%	>50%	<50%
Secondary indices of elevated RA pressure			Restrictive filling Tricuspid E/E' >6 Diastolic flow predominance in hepatic veins (systolic filling fraction <55%)	

Ranges are provided for low and intermediate categories, but for simplicity, midrange values of 3 mm Hg for normal and 8 mm Hg for intermediate are suggested. Intermediate (8 mm Hg) RA pressures may be downgraded to normal (3 mm Hg) if no secondary indices of elevated RA pressure are present, upgraded to high if minimal collapse with nasal inhalation (<35%) and secondary indices of elevated RA pressure are present, or left at 8 mm Hg if uncertain.

patient's esophagus via a manipulable flexible probe. Similar to transthoracic scanning, multiplane two- and three-dimensional, color flow, and spectral Doppler imaging can be performed at the bedside, but with a higher-frequency transducer than can typically be used transthoracically and from a position that is posterior and closer to the heart than can be achieved with TTE. The result is superior image quality and spatial resolution with less artifact, particularly when assessing the left atrium and left-sided valves, structures that are directly adjacent to the esophagus. Because it is semi-invasive, TEE is generally used as an adjunctive or follow-up test to an initial TTE if additional information is sought or the TTE images are inconclusive. **Table 14-9** summarizes the advantages and disadvantages of TTE versus TEE.

TEE is particularly useful in the evaluation of valve dysfunction, diagnosis or follow-up of endocarditis, searching for potential causes of stroke, and better characterization of cardiac masses and congenital heart disease. In some circumstances TEE is appropriately the first test of choice, such as evaluation of aortic pathology and assessment for LA appendage thrombi¹⁹ (see **Diseases of the Aorta** and **Cardiac Masses**). TEE can be used to determine the presence of thrombus in patients in whom rapid cardioversion of atrial fibrillation is necessary (see **Chapter 38**) or when elective atrial arrhythmia ablation/cardioversion is planned, particularly in circumstances in which the patient is found to be underanticoagulated or at high risk for stroke (**Table e14-1**).²⁰ In addition, TEE has a major role in optimizing and evaluating cardiac surgical and percutaneous procedures, particularly with respect to valvular procedures, closure of intracardiac shunts, and implantation of LV assist devices (LVADs).^{21,22}

TEE may be performed on an inpatient or outpatient basis, and most patients require topical anesthesia and/or intravenous conscious sedation for comfort. This is usually achieved with intravenous midazolam and fentanyl or alternatively with propofol if issues with respiratory or hemodynamic stability or patient comfort are

anticipated. General anesthesia is used for patients in the operating room. Risks are relatively low but include trauma to the oropharynx and esophagus, aspiration, bronchospasm or laryngospasm, accidental tracheal intubation, and arrhythmia, as well as risks associated with sedation (transient hypotension).²³ The most worrisome complication is upper gastrointestinal perforation, which most commonly occurs in the esophagus or hypopharynx. Patients with esophageal diverticular strictures, significant thoracic radiation-induced fibrosis, distorted anatomy of the mediastinal organs, or difficult probe placement are at higher risk. TEE may also cause bleeding (0.02% to 1.0%) from direct abrasion of the mucosa, esophageal varices, or tumor. The overall risk for major adverse events with TEE is 0.2% to 0.5% in the nonoperative setting, and the overall mortality rate is extremely low (0.0004%). These risks may be minimized by screening patients for potential contraindications (**Table e14-2**); if one is found, TEE is best deferred until the situation can be better assessed or ameliorated. Alternatively, another imaging modality (e.g., intravascular ultrasound [IVUS] or epiaortic scanning, CT, or CMR) or strategy could be considered if an underlying risk factor cannot be mitigated.

The Standard Transesophageal Echocardiographic Examination. A standard TEE examination is shown in **Figure 14-23**. It is usually prudent to address the main indication first in the event that the examination needs to be aborted because of clinical instability. If the patient remains stable, a comprehensive examination is carried out by first examining the heart with the probe at the midesophageal level. For a frame of reference with respect to the imaging planes, when the TEE transducer probe is midesophageal, at 0 to 30 degrees, and flexed, the imaging plane cuts the heart in a short-axis (transverse) plane. A TEE transducer angle of 90 to 120 degrees corresponds to a long-axis (longitudinal, or sagittal) plane. With the transducer plane dialed back to the original 0 degrees, either retroflexing the head of the TEE transducer or advancing it all the way to the apex of the heart

TABLE e14-1 Indications for Transesophageal Echocardiography–Guided Cardioversion

APPROPRIATE	INAPPROPRIATE
CHF exacerbation or hemodynamic compromise	Stable with therapeutic anticoagulation >3 weeks
Symptomatic from AF	AF <48 hours (insufficient time for thrombus to form)
Hospitalized and symptomatic	Permanent AF (sinus rhythm unable to be sustained after cardioversion)
New-onset AF (1st time diagnosis)	Hospitalized but asymptomatic
High stroke risk (including history of stroke or TIA, previous history of LA thrombus, rheumatic heart disease, HOCM)	
Subtherapeutic anticoagulation (INR <2 within preceding 3 weeks)	
Miscellaneous (including need for TEE unrelated to AF but otherwise appropriate, such as evaluation of valve function or endocarditis, with timing of TEE coincidentally helpful for expediting cardioversion)	

AF = atrial fibrillation; CHF = congestive heart failure; HOCM = hypertrophic obstructive cardiomyopathy; INR = international normalized ratio; TIA = transient ischemic attack.

TABLE e14-2 Relative Contraindications to Transesophageal Echocardiography and Potential Strategies

RELATIVE CONTRAINDICATION	POTENTIAL STRATEGIES
Esophageal strictures or diverticula	GI consultation to evaluate, consider use of a pediatric TEE probe or limited TEE only to a depth proximal to the lesion
Esophagitis, especially radiation induced	GI consultation to evaluate, consider alternative procedure
Esophageal varices or recent UGI bleeding	GI consultation to evaluate, correct any coagulopathy, limit TEE only to a depth proximal to the lesion, avoid unnecessary probe manipulation
Recent esophageal dilation or UGI surgery	GI/surgery consultation, consider delaying TEE to at least 4-6 weeks, consider limited TEE proximal to the intervention
Unstable airway and/or hemodynamically tenuous or unstable	Consider intubation and pressors
Unstable cervical spine (e.g., after trauma)	Stabilize with a cervical spine collar, consider paralysis, neurologic and/or orthopedic consultation to clear
Uncooperative patient, restricted cervical mobility	Anesthesia consultation for intravenous propofol, consider higher levels of sedation or general anesthesia
History of significant opioid use/abuse	Anesthesia consultation for intravenous propofol
Severe coagulopathy or thrombocytopenia	Consider correction with blood products and vitamin K

GI = gastrointestinal; UGI = upper GI.

**TABLE 14-9 Advantages and Disadvantages of Transesophageal Echocardiography Relative to Transthoracic Echocardiography**

ADVANTAGES	DISADVANTAGES
Useful in percutaneous and surgical procedures, as well as at the bedside	Semi-invasive—usually requires sedation, hence associated risks with probe intubation (gastrointestinal and pulmonary implications) and sedation effects (hypotension). Long procedures may necessitate general anesthesia. Generally a minimum of two staff members required: one operator and one person to monitor the sedation needed
Higher resolution: better to definitively diagnose or characterize vegetations, thrombi, masses, intracardiac shunts. Superior imaging of valves, especially the mitral and aortic, left atrium, left ventricle, aorta and arch, and interatrial septum, as well as the pulmonary veins	May not view the LV apex or right-sided structures well (structures that are further from probe, particularly in large patients)
“Continuous” acoustic window when compared with TTE (no ribs to cause shadowing)	“Blind spot” of acoustic shadowing where the trachea is interposed between the esophagus and heart Much of the abdominal aorta is out of range
Superior imaging of the mitral valve and mitral prostheses in general, with the ability to precisely localize valvular and paravalvular defects	Mechanical aortic prostheses can cause excessive shadowing May be technically difficult to achieve the best angle of insonation for interrogating aortic gradients (i.e., less reproducible for assessing aortic stenosis gradients) Maneuvers to increase or decrease preload may be more difficult (e.g., Valsalva maneuver), although most patients can cooperate Real-time three-dimensional imaging and reconstruction dependent on a slow regular heart rate and “stable” window (i.e., still patient)

while remaining flexed will cause the imaging plane to tilt into a four-chamber view.

Most examinations start with the standard four-chamber view of the heart, which is akin to the transthoracic apical four-chamber view with a TEE probe angle of 0 degrees. At this level the multiplane “omni” controller is used to rotate the scanning plane counterclockwise to slice the left ventricle into two-chamber (≈ 90 degrees) and then three-chamber (long-axis or ≈ 120 -degree) views. These views are optimal for assessing the left ventricle, left atrium, and mitral valve. If desired, the LA appendage may be thoroughly examined by withdrawing the probe slightly cephalad, centering the image sector on the appendage, and scanning from 30 to 150 degrees. To examine the aortic valve, the operator retracts the probe slightly and the aortic valve should be imaged just superior to the mitral valve, at approximately 30 degrees for short-axis images and 120 degrees for long-axis views. The tricuspid valve may be examined at approximately 45 degrees, with subsequent views of the RV outflow tract (RVOT), pulmonary artery and valve, and pulmonary bifurcation sought by gradually increasing the omni angle up toward 120 degrees again. Minor additional manipulations of the TEE probe and transducer angle will provide views of the pulmonary veins, right atrium, interatrial septum, superior vena cava (SVC), IVC, coronary sinus, and abdominal aorta. For transgastric windows, the TEE probe is advanced gently past the gastroesophageal sphincter with the transducer plane reset back to 0 degrees. One can view the left ventricle and mitral valve in the short axis and also obtain transaortic gradients from an apical five- or three-chamber view if needed. By increasing the omni angle up to 90 degrees and rotating the transducer plane to the right, more detailed views of the tricuspid valve and right side of the heart are attainable. Finally, the thoracic aorta is usually examined in cross-sectional and longitudinal views as the probe is withdrawn to document any significant atherosclerosis or other pathology.

THREE-DIMENSIONAL ECHOCARDIOGRAPHY

Acquisition and display of three-dimensional images have been a long-term goal of echocardiography. Although three-dimensional data sets can be obtained from transthoracic or transesophageal rotational acquisition, true three-dimensional echocardiography is accomplished by using a matrix-array transducer that emits and receives beams of ultrasound in two dimensions (**Fig. 14-24A**), which results in the acquisition of a pyramidal data set in three dimensions. Matrix-array probes for both transthoracic and transesophageal use are available. The three-dimensional data sets can be used to display simultaneous orthogonal two-dimensional images

(such as the four- and two-chamber apical views) or a three-dimensional rendered image (**Fig. 14-24**). Three-dimensional echocardiography offers the potential to better visualize valvular structures (see **Valvular Heart Disease**) or congenital abnormalities and can be particularly useful for surgical planning. Indeed, TEE-based three-dimensional imaging in the operating room is becoming particularly useful during cardiac valve surgery (see **Chapter 63**). Three-dimensional echocardiography can also improve quantification of LV and RV volume and ejection fraction because three-dimensional imaging is not subject to the volumetric assumptions and potential errors inherent with two-dimensional imaging. In part because current three-dimensional imaging is associated with loss of spatial and temporal resolution when compared with two-dimensional imaging, application of three-dimensional echocardiography outside the operating room is currently more limited. Still, current three-dimensional probes can function as two-dimensional probes without loss of image quality and better define the course and extent of complex structures. As technologic advances improve three-dimensional image quality, three-dimensional acquisition will probably become standard in echocardiography.

CONTRAST ECHOCARDIOGRAPHY

Contemporary echocardiographic contrast agents are stabilized gas microspheres that at 2 to 8 μm are similar in size to red blood cells and can move through the circulatory system similarly. Currently approved agents consist of perfluorocarbon gases, chosen because of their resistance to diffusion into the bloodstream; they are enclosed within either albumen or phospholipid shells. Unlike the larger bubbles created by agitating saline, commercial contrast bubbles are small enough to transit the pulmonary vascular bed and are therefore capable of opacifying the left side of the heart.

Because their shells are not rigid, contrast bubbles will contract in response to the peak acoustic pressure of the sinusoidal ultrasound wave and expand when acoustic pressure is at its trough. Optimal imaging of contrast agents is based on the way in which this oscillation in size varies with ultrasound system transmit powers (mechanical index). When exposed to sound waves at lower mechanical indices, the bubbles will undergo resonant oscillation in a linear fashion, but with higher transmit frequencies, the bubbles will resonate in a non-linear fashion. At even higher transmit powers, the bubbles will be destroyed, thereby generating very strong nonlinear backscatter of extremely short duration (**Fig. e14-7**). When the bubbles resonate in a linear fashion, they will behave as the surrounding tissue and reflect sound at the fundamental frequency, that is, the same frequency as was transmitted from the ultrasound system. When the

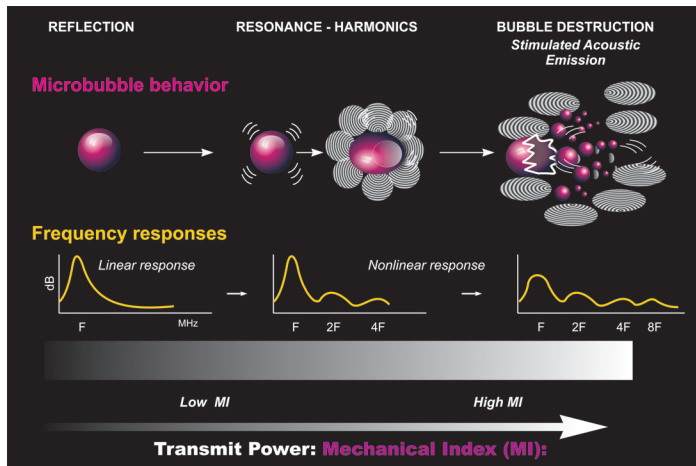

FIGURE e14-7 Principles of contrast-enhanced imaging.

FIGURE 14-23 A suggested standard TEE examination. Basic probe positioning, manipulations, and views are shown here. The sequence illustrated here allows a basic survey of all the cardiac chambers and valves. Additional views are obtained as required for the specific indication. Ao = aorta; AoV = aortic valve; Asc = ascending; AV = aortic valve; Desc = descending; LAX = long axis; ME = midesophageal; PV = pulmonic valve; SAX = short axis; TG = transgastric; TV = tricuspid valve; UE = upper esophageal.

bubbles resonate in a nonlinear fashion, sound is reflected both at the fundamental frequency and at harmonic frequencies, multiples of the fundamental frequency. Therefore to distinguish bubbles from surrounding tissue, ultrasound systems are set at mechanical indices (0.15 to 0.3)²⁴ that will generate nonlinear resonance without bubble destruction and with the ability to selectively receive harmonic frequencies, thereby improving the strength of the bubble signal relative to that of tissue (see Fig. e14-7).

By opacifying the blood pool, contrast agents improve detection of the endocardial-blood pool interface and thus facilitate assessment of ventricular volume, as well as global and regional ventricular function (Fig. 14-25). It has been demonstrated that contrast agents can convert nondiagnostic (defined as inadequate visualization of

two or more of six LV segments seen on apical views) to diagnostic studies in up to 90% of patients. This can be particularly helpful in the intensive care unit, as well as with stress echocardiography, in which obtaining adequate images in the immediate postexercise period may be challenging. By better delineating the cardiac anatomy, contrast agents facilitate the identification of aneurysms and diverticula, mechanical complications of MI such as free wall rupture and pseudoaneurysms, apical hypertrophy, transient apical ballooning, endomyocardial fibrosis, and the prominent crevices that characterize noncompaction cardiomyopathy. They are also helpful in detecting intracardiac masses such as thrombi and tumors and assessing their vascularity. In addition, contrast agents may help distinguish imaging artifact from pathology (Fig. 14-26). Despite being considered

FIGURE 14-24 Three-dimensional (3D) echocardiography using a matrix-array transducer. A waffle-like matrix array (left panel) is used to obtain pyramidal “volumes” for real-time 3D data sets that can be cropped (right panel) and rendered in three dimensions. Alternatively, two-dimensional planes can be “cut” through any part of the 3D data set. A4C = apical four chamber. (Modified from Bulwer BE, Rivero JM [eds]: *Echocardiography Pocket Guide: The Transthoracic Examination*. Burlington, Mass, Jones & Bartlett Learning, 2011, 2013, p 208. Reprinted with permission.)

FIGURE 14-25 Unenhanced (left panel) and contrast-enhanced (right panel) apical four-chamber systolic images. In the unenhanced image it is impossible to define the endocardium, whereas with contrast enhancement the endocardium is clearly delineated and the straight margin characteristic of a sessile apical thrombus (arrow) is appreciated.

off-label use, contrast agents may be used to intensify spectral Doppler signals, which may be particularly helpful in delineating trans-valvular gradients in aortic stenosis (Fig. 14-27), and can delineate extracardiac pathology such as vascular dissection. Finally, in patients undergoing alcohol septal ablation for obstructive HCM (see Chapters 56 and 66), contrast agents are used to delineate the perfusion bed of target septal perforators.

Myocardial perfusion contrast-enhanced echocardiography is another application that is based on the ability of ultrasound to detect contrast bubbles within the myocardial vasculature. Approaches depend on the fact that a burst of ultrasound with a high mechanical index will predictably destroy microbubbles and that the rate at which myocardial contrast will subsequently be replenished is dependent on myocardial blood flow (Fig. 14-28). Two general approaches can be taken to imaging following the high-mechanical index flash:

low-mechanical index real-time imaging, which has the advantage of preserving information concerning wall motion, and a higher-mechanical imaging-triggered approach, which arguably provides better perfusion information at the expense of wall motion. Although myocardial perfusion imaging has been shown to be of value in both rest and stress imaging for detecting ischemia (Fig. e14-8) and identifying viable but stunned or hibernating myocardium,²⁵ contrast perfusion imaging is currently an experimental technique.

ECHOCARDIOGRAPHY IN THE CONTEXT OF CARDIAC IMAGING

The arsenal of noninvasive cardiovascular imaging modalities includes nuclear imaging (single photon emission CT [SPECT] and positron emission tomography [PET]), cardiac CT, and CMR (see Chapters 16, 17, and 18) and will undoubtedly continue to expand. Of these choices, echocardiography continues to hold the

major advantage of being the most rapid, portable, and real-time imaging modality available today. Hence TTE or TEE is often the first tool to be put into play in emergency situations such as cardiac tamponade, aortic dissection, peri-infarct or postoperative complication, and shock, in which rapid assessment of a very unstable patient may be carried out at the bedside. When a large number of patients need to be screened or patients need to be monitored long-term with serial examinations, the fact that ultrasound imaging involves no ionizing radiation is a particularly important consideration. It is thus ideal for monitoring valvular dysfunction, cardiotoxic chemotherapy, and cardiomyopathies. Even though the spatial resolution of other modalities such as CMR or CT may be greater than that of echocardiography, the superior temporal resolution of TTE and TEE make these techniques ideal for detection of small mobile vegetations, thrombi, and fibrinous strands in the heart, which move too rapidly to be easily visualized by techniques with slower frame rates.

Stress echocardiography using either treadmill, bicycle, or pharmacologic (dobutamine or vasodilator) stress has proved to be more accurate than the exercise ECG alone for diagnosing flow-limiting CAD, particularly in women and patients with LV hypertrophy. When compared with nuclear imaging, stress echocardiography is equally sensitive and specific. However, the presence of previous infarcted segments, known multivessel CAD, and a left bundle branch block may decrease the sensitivity and specificity of stress echocardiography because of difficulty interpreting wall thickening in the presence of resting regional dysfunction and translational motion.²⁶

In addition to diagnosing structural abnormalities of the myocardium, pericardium, valves, and vessels, echocardiography can directly demonstrate the consequent physiologic and hemodynamic derangements. This is particularly true for pericardial effusions (see Chapter 71), in which echocardiography can demonstrate impending or actual tamponade in real time within seconds. For more refined tissue characterization, CMR often offers higher resolution and specificity in defining tumor characteristics such as tissue density and vascularity, infiltrative/inflammatory processes, and nontransmural fibrosis. CT is particularly useful in defining calcified cardiac structures, and CT angiography is capable of imaging the coronary arteries along their full extent far more reliably than echocardiography can (provided that the patient has a relatively slow and regular heart rate). Defining the thickness of the pericardium is also another

FIGURE e14-8 Apical three-chamber views showing real-time myocardial perfusion imaging. **Left**, Unenhanced baseline immediately after a high-mechanical index impulse flash. **Right**, Uniform enhancement consistent with normal perfusion. (Courtesy F. Xie and T. Porter; University of Nebraska Medical Center.)

FIGURE 14-26 Apical four-chamber unenhanced (left panel) and enhanced (right panel) images. In the unenhanced image a thrombus-like structure is visualized in the apical region (arrow). The enhanced version shows that there is no filling defect, thus suggesting that this was an acoustic artifact and not a true thrombus.

FIGURE 14-27 Baseline unenhanced Doppler spectra (left panel) in this patient with valvular aortic stenosis are indistinct. Following administration of contrast material (right panel), the CW spectra are clearly defined.

“Achilles heel” of echocardiography. It has been demonstrated that cardiac ultrasound is poorly sensitive for pericardial thickening and that CT and CMR provide a more sensitive and comprehensive method of evaluation. However, echocardiography remains the first-line modality for detecting the characteristic respirophasic septal bounce and respiratory variations in cardiac output caused by constriction and continues to be the mainstay of follow-up regardless of treatment.²⁷

Acoustic shadowing from prosthetic valvular structures, ventricular assist devices (VADs), calcification, or air between the transducer and the distal portions of the heart can preclude adequate visualization of portions of the heart by echocardiography, and in these cases radiologic modalities such as fluoroscopy and CT can be alternative or adjunctive modalities. Similarly, because the sternum and

ribs impede transthoracic ultrasound imaging and the air-filled trachea produces a “blind spot” on TEE, echocardiographic evaluation of the aorta is limited to the proximal root, arch, and segments of the thoracic and abdominal aorta. However, if the patient is unstable (e.g., after a motor vehicle accident or in cardiogenic shock), TTE and/or TEE is often the only suitable bedside tool and is sufficient to rapidly diagnose or rule out most type A dissections (see Chapter 57). With TEE one can also rapidly determine whether the proximal coronary arteries and arch vessels are patent without the use of intravenous contrast material.

It should be emphasized that in many cases the use of two or even more modalities is appropriate and complementary to more definitively characterize the nature and extent of an abnormality and plan appropriate treatment. This is particularly true in cases of ischemic and nonischemic cardiomyopathy,²⁸ for which CMR and SPECT/PET can more clearly define the locations of hypertrophy, fibrosis, or inflammation. Extensive aortic dissections in which one needs to precisely define the extent to which major coronary, head, and systemic arteries are involved also often calls for multimodality imaging.

Echocardiography can unfortunately render a variety of artifacts that produce the false appearance of masses mimicking thrombi, tumors, or mobile tissue flaps; although most can be discerned as false findings by experienced sonographers, a minority may require additional tailored echocardiographic views, often in different tissue planes, to put the question to rest. The use of three-dimensional echocardiography and/or intravenous echocardiographic contrast agents can clarify many of these echocardiographic artifacts without the potentially nephrotoxic effects of the iodinated and gadolinium agents used in radiologic imaging.

Currently, there are also newer techniques that have evolved in almost parallel fashion in echocardiography and CMR for quantitatively assessing tissue strain, dyssynchrony, and diastolic function.²⁹ These techniques have been used extensively in research and are beginning to be validated in a clinical setting with larger populations. In summary, although advances in the capability of ultrasound and radiology continue to grow, familiarity with the relative advantages and limitations of each imaging modality can help determine which tool is most suitable for answering the clinical question at hand.

MYOCARDIAL INFARCTION

Echocardiography plays an essential diagnostic and prognostic role in assessing patients during and after acute MI. Normal wall contractility (normokinesis) is seen as wall thickening caused by the contraction of individual myocardial fibers during systole. On echocardiography the radial distance between the epicardial and endocardial borders normally increases by at least 20% during systole. Global LVEF, as calculated by two-dimensional echocardiography and preferably by the two-dimensional biplane method of discs, provides an indication of overall infarct size and location. It has remained the single measure with the greatest prognostic and clinical significance during and following MI.

Myocardial ischemia affects LV systolic function both focally and globally. Focal hypokinesis—decreased systolic thickening—occurs within seconds of the onset of myocardial ischemia, before chest pain and changes on the ECG (see Chapter 49). This pathognomonic finding will occur in the region of the left and/or right ventricle supplied by the compromised artery (at least 70% stenosis) and give the appearance of a hinge point when compared with adjacent perfused segments. Ischemia may also be manifested as delayed contractility of a segment. Ischemia is a dynamic condition, and if sufficient blood flow is restored in time (either through a decrease in metabolic demand as when a stress test ends or through reperfusion), contractility of the affected segment can recover rapidly. However, in the setting of reperfusion therapy, a marked reduction in LVEF during the initial few days after MI can be secondary to myocardial stunning rather than permanent

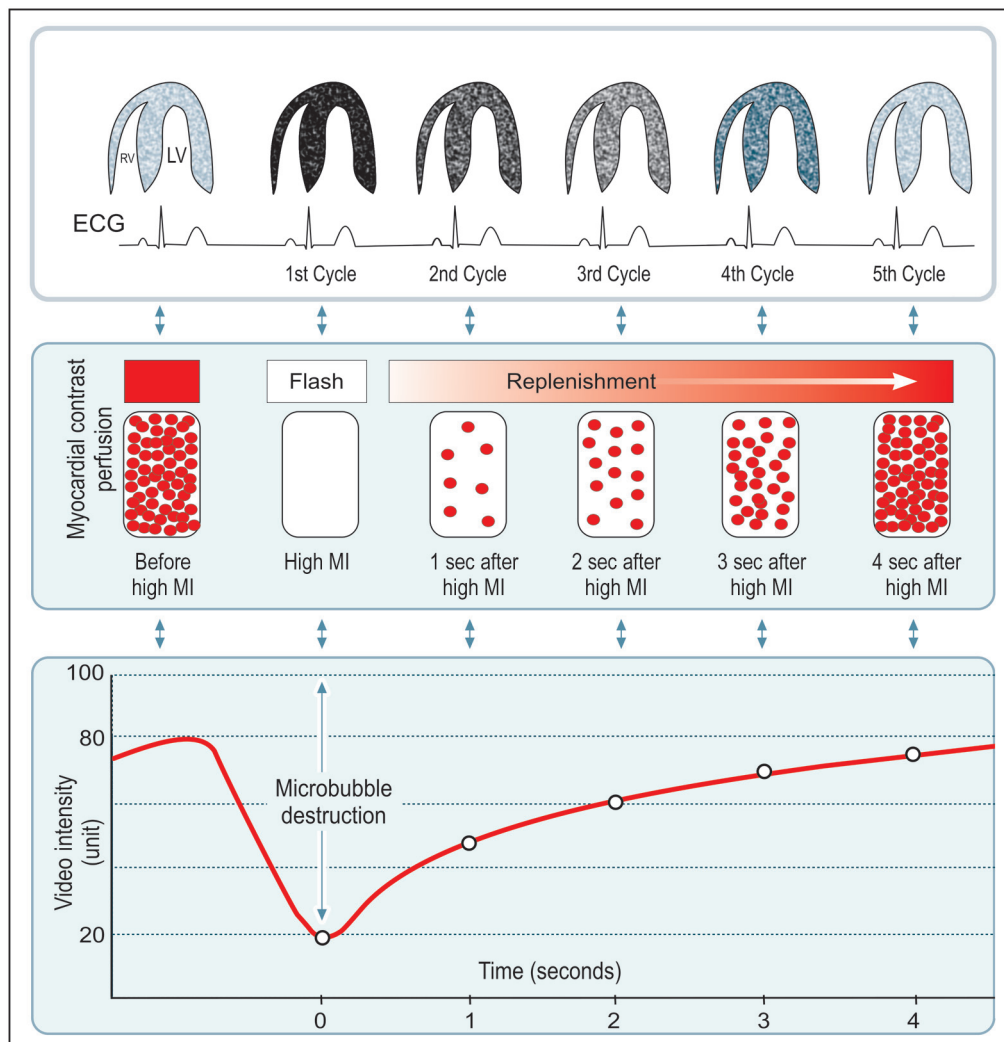

FIGURE 14-28 Myocardial contrast-enhanced echocardiography: schematic demonstrating the approach to myocardial perfusion imaging during steady-state infusion of a contrast agent. A high-mechanical index impulse (MI) destroys all the intramyocardial bubbles to yield an unenhanced image that will serve as the reference baseline. Subsequently, bubbles will return to and progressively enhance the myocardium until a steady-state concentration is reached. This may be monitored by either a triggered approach in which imaging is performed on end-systolic images at increasing numbers of beats after the flash (1, 2, 3, 4, etc.) or by using low-mechanical index continuous imaging. Enhancement will increase until a steady-state level is achieved (in this hypothetical example at a five-beat pulsing interval or after 4 seconds of low-MI imaging). The rate at which replenishment occurs and the degree of enhancement under steady-state conditions, as can be quantitated by video intensity, reflect myocardial perfusion. LV = left ventricle; RV = right ventricle. (Modified from Wei K, Jayaweera AR, Firoozan S, et al: Quantification of myocardial blood flow with ultrasound-induced destruction of microbubbles administered as a constant venous infusion. *Circulation* 97:473, 1998.)

myocardial dysfunction and can improve substantially over a period of days to weeks (see Chapter 49).^{30,31}

Persistence or increasing severity of the wall motion abnormality after the initial insult implies that the tissue is becoming nonfunctional (i.e., not metabolically active or hibernating) or nonviable (infarcted). Akinetic myocardial segments do not thicken at all, and dyskinetic segments bulge paradoxically outward in systole, thus implying that no functioning myocardium is present. Thinning of the walls to less than 6 mm, echobrightness, and dyskinesis usually indicate scar. Sudden dilation of the left ventricle and a decrease in the LVEF are predictive signs of larger areas of ischemia (more proximal and/or multivessel). More refined techniques, including intravenous echocardiographic contrast enhancement to examine myocardial perfusion, low-dose dobutamine echocardiography, or regional strain analysis, may be useful in demonstrating whether segments that are still akinetic after reperfusion remain viable but hibernating.³²

Specific regions in the heart can be mapped to specific coronary artery territories (Fig. 14-29), thereby allowing determination of the infarct-related vessel in patients with MI or detection of ischemic territory during stress echocardiography (see the section **Stress**

Echocardiography). A proximal coronary artery stenosis will cause wall motion abnormality in a large territory (i.e., an entire wall from base to apex), whereas more distal blockage will affect only more apical segments. An acute left main occlusion will result in such extensive dysfunction (anterior septum, anterior and lateral walls) that if untreated, is usually lethal. Proximal right coronary artery (RCA) lesions can additionally cause RV dysfunction and infarction. The presence of previously existing CAD can modify the extent of new wall motion abnormalities seen during acute MI. Small collateral vessels from other unobstructed coronary arteries can develop and perfuse the peripheral territory of affected vessels, thus diminishing the dysfunctional territory. Wall motion scoring can be used as a complementary tool to the ejection fraction for quantifying the extent and severity of LV systolic function (see Fig. e14-4).

Practical Considerations in Assessment of Regional Wall Motion. It is important to carefully distinguish between wall thickening as opposed to just epicardial or endocardial border movement during systole. Pitfalls in diagnosing wall motion abnormalities abound; they include false positives because of poor visualization of the endocardium, superior angulation of the probe such that the membranous, nonmuscular portion of the upper interventricular

FIGURE 14-29 Coronary artery territories. The main epicardial coronary arteries each supply distinct myocardial territories, which may be mapped and evaluated during the ultrasound examination. For standardization, the left ventricle (LV) is divided along the long axis into anterior, inferior, septal, and lateral quadrants. At the basal and midventricular levels, the septal and lateral walls are further subdivided into anterior and inferior segments. Each wall is further sectioned in short-axis planes into basal, mid, and apical thirds, with the distal apex beyond the LV cavity forming a cap segment to yield a total of 17 wall segments. Most of the blood supply to the heart is from the left main coronary artery, which divides into the LAD and left circumflex (LCx) arteries. The LAD supplies most of the anterior ventricular wall, and its septal branches supply the anterior two thirds of the septum. In addition, diagonal branches of the LAD supply the anterolateral wall. Large LADs may wrap around the apex of the heart and supply the distal-most portion of the inferior wall. The LCx runs in the atrioventricular groove, and its obtuse marginal branches supply the inferolateral wall. The RCA supplies blood to the inferior third of the septum and the inferior wall. The RCA also supplies the right ventricle. A2C = apical two chamber; A4C = apical four chamber; LA = left atrium; PDA = posterior descending artery; PLAX = parasternal long axis; RA = right atrium; RV = right ventricle. (Modified from Bulwer BE, Rivero JM [eds]: *Echocardiography Pocket Guide: The Transthoracic Examination*. Burlington, Mass, Jones & Bartlett Learning, 2011, 2013, p 131. Reprinted with permission.)

septum is misinterpreted as a nonmoving myocardial segment, extracardiac compression of the inferior wall by ascites or abdominal contents ("pseudodyskinesia"), and paradoxical or dyssynchronous septal motion as a result of bundle branch block or the postsurgical state. False negatives, such as missing a wall motion abnormality that is present, can also occur because of poor image quality or off-axis imaging. In some cases, injection of an intravenous contrast agent can help delineate the endocardial borders.

It is important to recognize that echocardiography in a patient who is free of chest pain at the time of imaging may not reveal a resting wall motion abnormality (because of decreased demand or reperfusion) and that this technique is relatively insensitive for small areas of subendocardial or microvascular ischemia. Nevertheless, when a patient has ongoing acute chest pain but echocardiography does not reveal new wall motion abnormalities, a broader differential diagnosis than epicardial coronary artery occlusion must be entertained. Possible nonischemic cardiac causes of chest pain that can be also diagnosed by cardiac ultrasound include pericarditis, aortic or coronary aneurysm or dissection, myocarditis, cardiac contusion, and ruptured mitral chordae. Noncardiac causes include pulmonary emboli (which can cause acute right-sided heart dysfunction in a distinctive pattern), as well as gastroenterologic processes (e.g., reflux, peptic ulcer disease, esophageal spasm), pleuritis, and costochondritis.

Mechanical Complications after Myocardial Infarction (see Chapter 52)

MI can cause serious collateral damage from tissue necrosis and bleeding, which is often heralded by cardiogenic shock. These events may appear within days of the initial infarct or may be delayed by years. All cardiologists should be familiar with causes of infarct-related shock and their appearance on echocardiography (Fig. 14-30). Indications for echocardiography after MI are detailed in the appropriate use criteria developed by the American College of Cardiology and other societies (see Chapter 14G).¹⁹

Acute severe mitral regurgitation (MR) is most often caused by infarction and consequent rupture of a papillary muscle. It results in "flail" of the associated mitral leaflet into the left atrium during systole with valve incompetence (Fig. 14-31; see also Fig. 14-30A). The anterolateral papillary muscle receives dual blood supply from both the left anterior descending (LAD) coronary artery and its diagonals and the left circumflex artery (see Chapter 20); thus a very large infarct would be required to disrupt this papillary muscle, which supports more of the anterior mitral leaflet. In contrast, the posterior descending artery, which arises from the RCA in right-dominant individuals, supplies solely the posteromedial papillary muscle. For this reason, papillary muscle rupture and flail posterior leaflet occur more commonly with inferior infarcts. There is, however, overlap between the papillary muscle support of the leaflets, and only one head or a tip of a papillary muscle may be disrupted rather than the entire trunk. Hence in small infarcts there

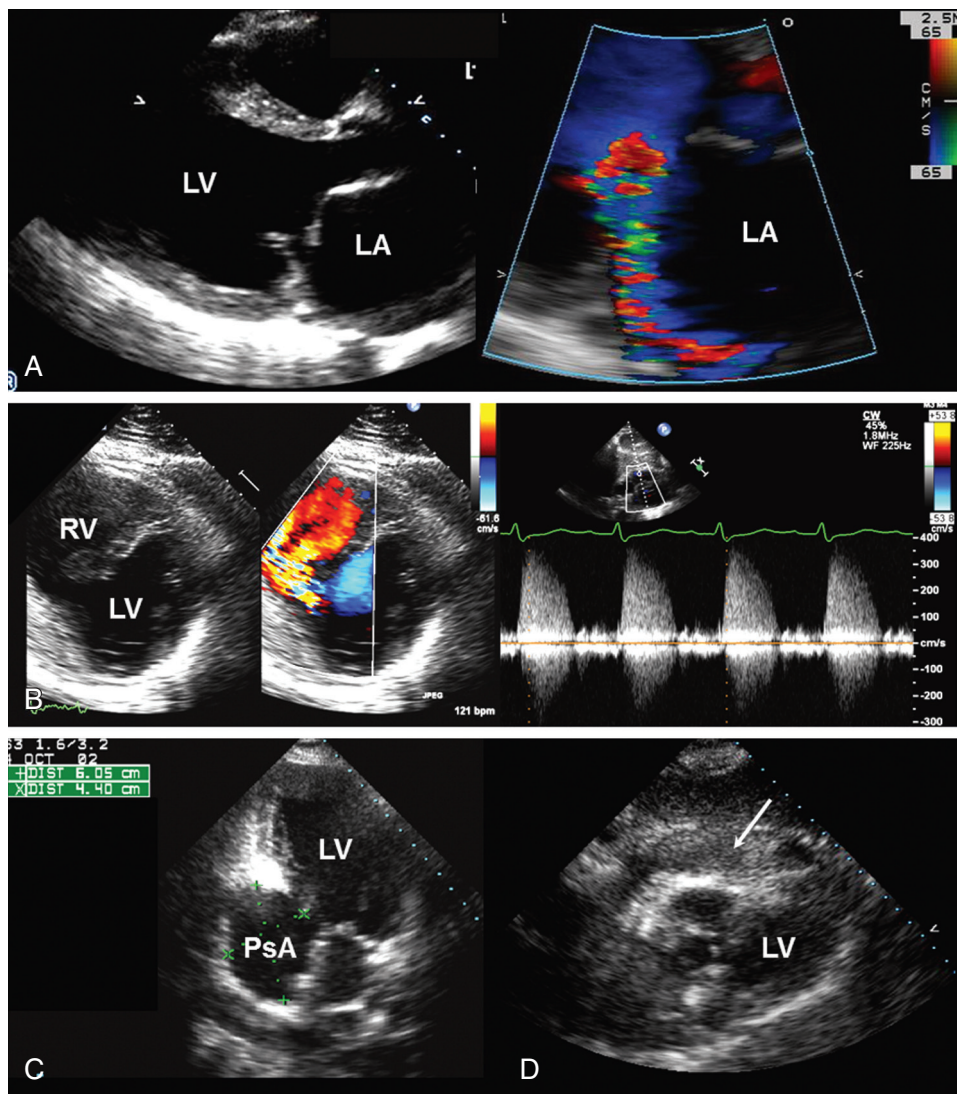

FIGURE 14-30 Acute complications of myocardial infarction. **A**, Flail mitral leaflet (left panel) with severe mitral regurgitation (right panel). **B**, Ventricular septal defect (left panel) in the basal inferoseptum with (right panel) an intraventricular pressure gradient of 58 mm Hg by spectral Doppler. **C**, Pseudoaneurysm (PsA) of the basal inferior wall. **D**, Hemopericardium (arrow) caused by free wall rupture. LA = left atrium; LV = left ventricle; RV = right ventricle.

may be a focally flail segment or just the tip of an opposing mitral leaflet affected. The jet of MR is eccentric and directed *away* from the affected mitral leaflet; that is, posterior leaflet flail directs the MR jet anteroseptally, whereas anterior leaflet flail directs the regurgitant jet posterolaterally (see Figs. 14-30 and 14-31). If clinical suspicion for acute infarct-related MR is high and TTE is not definitive, proceeding expeditiously to surgical consultation and TEE is recommended.

Ventricular Septal Defect

Defects in the ventricular septum may appear as discrete areas of echo dropout with interventricular flow coursing through, as demonstrated by color Doppler (see Fig. 14-30B). Echocardiography should define the location, type (simple or complex), and size of the defect. Anterior ventricular septal defects (VSDs) tend to be simple (i.e., direct slitlike perforations through both sides of the septum at the same level) and are usually located more apically. In contrast, inferior infarctions often involve the adjacent basal inferior septum or even the right ventricle and can be complex (with serpiginous or multiple fissures). Unless the defect is very large, two-dimensional echocardiographic images alone may only be suggestive of thinned or focally absent myocardium, but color flow Doppler can definitively

FIGURE 14-31 Acute structural MR. The consequences of rupture of the posterior papillary muscle and chords (**upper figure**) versus the anterior papillary muscle and chords (**lower figure**) are shown with respect to the direction of the MR jet. Posterior mitral leaflet flail will cause a very eccentric jet to be directed anteroseptally, and this can occasionally cause clinicians to erroneously detect a “new aortic stenosis” murmur. Anterior mitral leaflet flail will cause the MR jet to be directed inferolaterally, and this murmur may be missed unless one auscultates the posterior thorax region. A4C = apical four chamber; Ao = aorta; LA = left atrium; LV = left ventricle; PLAX = parasternal long axis; RA = right atrium; RV = right ventricle.

demonstrate both the location and extent of the shunt at the “break” area. A small (restrictive) VSD will have a high interventricular pressure gradient, whereas a large (unrestrictive) VSD will have lower gradients and is more likely to be associated with further tissue damage, including even papillary muscle rupture or free wall rupture in catastrophic cases. By applying the Bernoulli equation the pressure gradient across a restrictive VSD can be calculated. RV systolic pressure should be equal to systolic blood pressure minus the interventricular pressure gradient. Significant and prolonged shunting across the VSD can lead to biventricular failure and eventually cause right-sided pressures to increase and the amount of left-to-right shunting to paradoxically decrease over time.

Pseudoaneurysm

A pseudoaneurysm is a ventricular free wall perforation that is locally contained by adjacent pericardium and adhesions. Pseudoaneurysms appear more commonly after inferior MI, although they may arise in the lateral and apical regions. On echocardiography they appear as echo-free spaces or extra chambers adjacent to and continuous with the LV cavity (see Fig. 14-30C). The appearance can be similar to that of a true LV aneurysm or diverticulum, but unlike these two pathologies, the definitive feature of a pseudoaneurysm is disruption of all three layers: endocardium, myocardium, and epicardium. Thus a pseudoaneurysm is more likely to have distinguishing traits such as a narrower neck with more ragged edges and turbulent bidirectional flow (as opposed to the smoother margins and flow pattern typically seen with true aneurysms). However, no single echocardiographic criterion is specific enough to accurately distinguish false from true LV aneurysms. Intravenous echocardiographic contrast agents can be very helpful in delineating the area of the perforation and extravasation into the pericardial space if the patient is sufficiently stable. Although pseudoaneurysms are typically subacute

complications of MI and may hemorrhage suddenly, some pseudoaneurysms are surprisingly stable and go undetected for years. In stable patients, CMR or even angiography is often useful in distinguishing pseudoaneurysm from aneurysm.

Free Wall Rupture

Free wall rupture is usually so acutely lethal that it is rarely imaged, but findings consist of a sudden new pericardial effusion in a patient with marked thinning and akinesis at the terminal myocardial territory of the occluded artery. Echocardiographic features of tamponade are usually present. The pericardial effusion may have spontaneous echocardiographic contrast or contain clot (hemopericardium). Demonstration of low-velocity color Doppler flow or extravasation of intravenous echocardiographic contrast from the LV cavity into the effusion would confirm wall rupture, but care must be taken to not confuse rupture with the low-velocity color signal generated within pericardial fluid by the adjacent moving heart.

Tamponade

Mechanical causes of tamponade related to infarcts include pseudoaneurysm and free wall rupture as described earlier, but also aortic dissection (in some cases caused iatrogenically by percutaneous intervention). All cause frank bleeding into the

pericardial sac. Hemopericardium is associated with a distinctive gel-like appearance of pericardial fluid on echocardiography (see Fig. 14-30D). In some cases, fully organized thrombus has been found in otherwise echolucent pericardial effusions and is thought to be indicative of past wall rupture that has been sealed off in the interim.

Other Causes of Cardiogenic Shock in Myocardial Infarction

In addition to the mechanical complications described earlier, there are other potential explanations for hypotension in the setting of acute MI. Simple loss of pump function in large infarcts is probably the most common reason. RV infarction (see Chapter 52) can occur concomitantly with inferoposterior injury or as isolated RV injury in a patient with occlusion of a nondominant RCA. It may reveal itself when nitroglycerin is administered and decreases preload. The most reliable echocardiographic sign of RV infarction is new dilation and hypokinesis of the right ventricle. Typically, the lateral or posterior RV walls are most affected (the posterior wall represents the distal-most RCA territory), with sparing of the apex (which is also supplied by the distal LAD). Depressed RV function can often be illustrated by a low tissue Doppler peak velocity of the tricuspid annulus at systole or by a slow upstroke to the tricuspid regurgitant Doppler envelope (low dP/dT) and be quantified by a low RV ejection fraction or FAC.³³ Annular dilation may cause associated TR and RA dilation with relatively low or normal peak TR flow velocity (because of low or normal RV systolic pressure). Because RV walls are thinner than those of the left ventricle, the right ventricle can recover relatively quickly from ischemic insults and return to normal function after revascularization. Other potential causes of hypotension and cardiogenic shock include reocclusion of coronary arteries with infarct expansion, related effusive pericarditis (Dressler syndrome), and acute dynamic LVOT obstruction with mitral systolic anterior motion when the basal

portion of the heart becomes hypercontractile in response to more apical wall motion abnormalities in patients with upper septal hypertrophy.

Late Complications of Myocardial Infarction

Even after a MI is completed, ongoing changes in heart structure and function can cause negative sequelae that can be clinically silent. *LV aneurysms* are discrete dyskinetic outpouchings of the left ventricle with preservation of the integrity of the three heart layers (endocardium, myocardium, and epicardium). The most common locations of LV aneurysms are the basal inferior wall and the apex, where they may grow to a size that rivals the other cardiac chambers. Spontaneous echocardiographic contrast within the aneurysms signifies local stasis of blood flow.

In the absence of anticoagulation, ongoing sluggish flow within an LV aneurysm may lead to the formation of *LV thrombus* (Fig. 14-32A).

Patients with large aneurysms, anterior MIs, or LVEF lower than 40% are at particular risk for this complication. Intracavitary thrombi may be detected within the first 1 to 2 weeks after MI and appear as discrete homogeneously echogenic deformable masses abutting the endocardial border of an akinetic or dyskinetic wall segment. Earlier studies indicated that the sensitivity and positive predictive value of echocardiography for LV thrombus were 95% and 86%, respectively, when compared with surgical/pathologic or radionuclide imaging. However, when compared more recently with CMR, the sensitivity (60%) and positive predictive value (75%) appear to be significantly less than originally assumed. Accuracy is undoubtedly affected by pretest probability, image quality, and the size and type of thrombus (the mural type being more difficult to detect).³⁴ The use of intravenous echocardiographic contrast material can double the detection rate of intracavitary thrombi and is highly recommended (see Fig. 14-25). Thrombi may appear mural (i.e., fixed, flattened, and adherent to the endocardial wall, as in Fig. 14-32A) or may have independently mobile and protuberant portions.

Larger and more mobile thrombi, as well as those residing adjacent to hyperkinetic myocardial segments, are more likely to embolize. As the thrombi age, they tend to become less mobile, more compact, and echobright in appearance. With anticoagulation, LV thrombi have been observed to resolve in almost 50% of patients by 1 year and in approximately 75% by 2 years of follow-up.

The left ventricle can continue to expand in size and mass and display hypokinesis in noninfarcted areas, even after the initial insult has ended, a process termed *LV remodeling*. In the broadest context, remodeling is defined as an increase in LV volume, but concomitant changes in the geometry of the ventricle are also frequently observed. An increase in the globular shape of the heart is quantified by the sphericity index. On two-dimensional echocardiography this is the ratio of the long-axis dimension to the short-axis dimension, and values are 1.5 or higher in normal hearts but approach 1.0 in globular hearts (see the *Dilated Cardiomyopathies* section, later).

Ischemic MR refers to mitral incompetence in the setting of ischemic LV dysfunction and in the absence of structural abnormalities, such as prolapse, thickening, or calcification, that would otherwise cause regurgitation (see Chapter 63). This process has been intensively studied, and there appears to be interplay between the LV, mitral, and subvalvular components, as well as the left atrium, all of which contribute to the pathophysiology of MR. Displacement of the papillary muscle positions inferiorly and toward the apex also contributes to tethering of the mitral leaflets at abnormal angles that restrict leaflet closure. Mitral annular and LA dilation, as well as insufficient mitral leaflet area to compensate for the enlarged orifice, appears to play a role in enhancing ischemic MR as well (Fig. 14-32B).³⁵ The effective regurgitant orifice area (EROA) is a simple measure of the degree of mitral insufficiency derived from color and spectral Doppler measurements and has a direct correlation with overall mortality (see *Mitral Regurgitation*).

Echocardiographic Prognostic Indicators after Myocardial Infarction

After acute MI, echocardiography can assist in assessing (1) the prognosis for

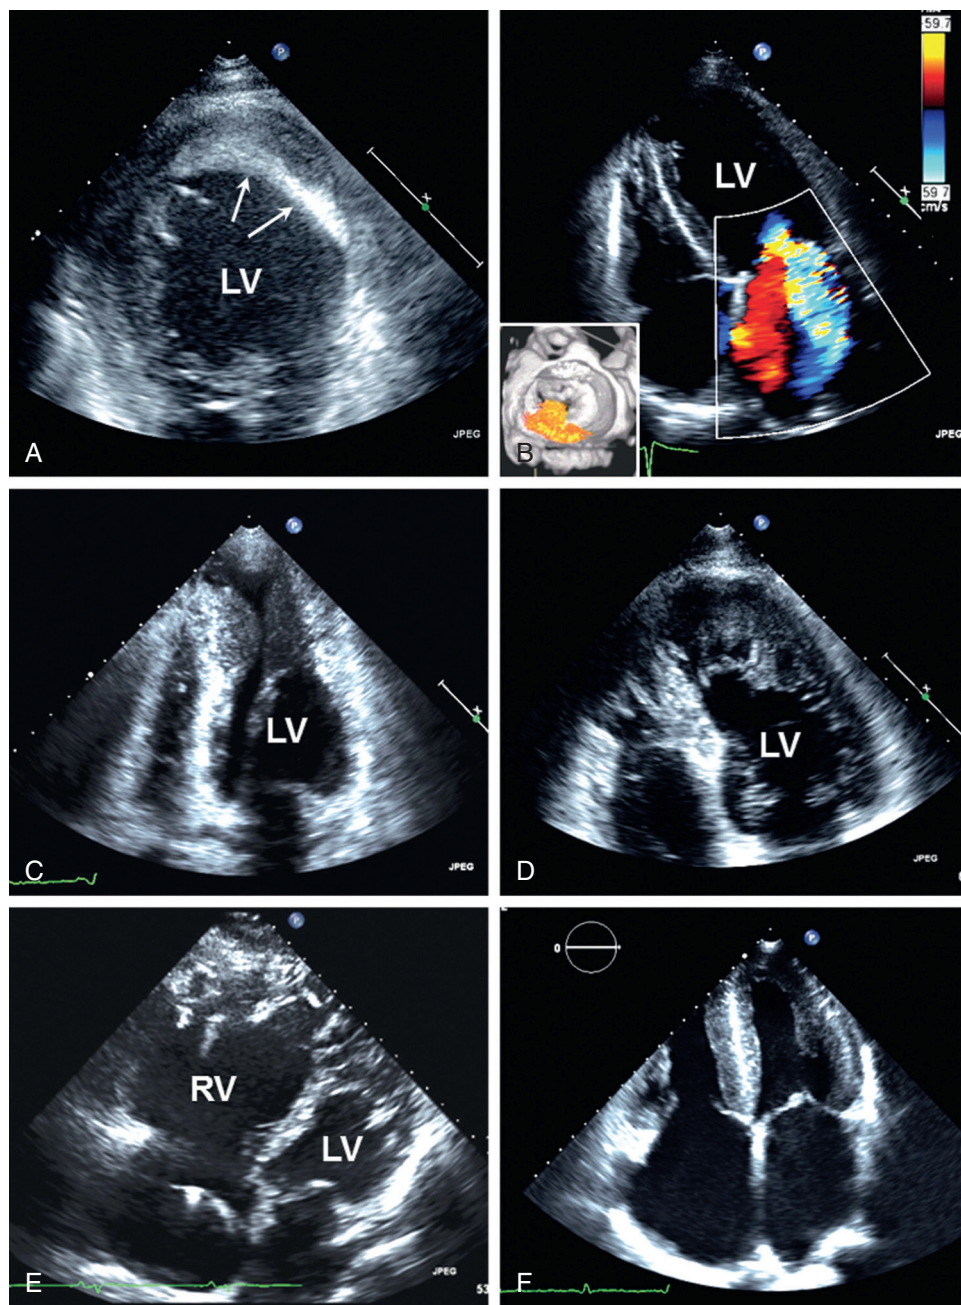

FIGURE 14-32 Cardiomyopathies. **A**, Ischemic cardiomyopathy illustrating an apical aneurysm and thrombus (arrows). **B**, Ischemic cardiomyopathy illustrating severe functional MR. **C**, Apical HCM with midcavity systolic obliteration and an apical aneurysm. **D**, LV noncompaction. **E**, Arrhythmogenic RV dysplasia. **F**, Amyloid heart disease. LV = left ventricle; RV = right ventricle.

patients at risk for recurrent ischemia and heart failure and (2) overall risk for morbidity and mortality.

LVEF is one of the most important predictors of overall morbidity and mortality after acute MI and is used as a surrogate endpoint in most major clinical trials of medical and procedural interventions. As LVEF declines, the rate of sudden cardiac death (SCD) increases. Based on current evidence the incidence of SCD at an LVEF of 35% or less is high enough to consider implantation of an implantable cardioverter-defibrillator (see Chapters 25 and 26) for primary prevention in selected patients with intraventricular conduction delay and heart failure.³⁶ As mentioned previously, it is important to recognize that functional recovery of stunned myocardium can occur after reperfusion and lead to an improvement in LVEF when measured 2 to 6 weeks after revascularization. In addition to LVEF, overall LV size (as assessed by LV end-diastolic volume and diameter) and sphericity are important prognostic indicators. Other measures that are independently predictive of heart failure in patients with stable CAD include increasing LV mass index (LVMI >90 g/m²), a pseudonormalized or restrictive pattern of diastolic dysfunction, an LVOT VTI of less than 22 mm, and an LA volume index higher than 29 mL/m². The presence of even mild MR is also an independent predictor of cardiac mortality, as well as heart failure or recurrent MI.^{35,37}

The WMSI may be a more discriminatory measure than LVEF (as measured by echocardiography or nuclear methods) in predicting cardiac events, in particular, rehospitalization for heart failure. On resting echocardiography, a WMSI higher than 1.7 that persists after treatment of MI suggests a substantial (>20%) perfusion defect and increased risk for complications. In stress echocardiography, a WMSI higher than 1.7 at peak stress and an ejection fraction of 45% or less are independent markers of patients at high risk for recurrent MI or cardiac death. When there is a question of whether revascularization will improve akinetic but viable areas, dobutamine or contrast-enhanced echocardiography may delineate the extent of myocardium that is hibernating (hypocontractile yet viable and still perfused³²). (See [Stress Echocardiography](#).)

Finally, it should be noted that wall motion abnormalities are indicative of focal myocardial dysfunction but are not entirely specific for atherosclerosis-related MI. Vasospasm, inflammation or fibrosis secondary to myocarditis, swelling from intramural hematoma or edema, takotsubo cardiomyopathy (apical ballooning syndrome, see Chapter 65), and any focal myocardial insult are also causes of wall motion abnormality. A comprehensive synthesis of the history, clinical and physical examination findings, and ECG together with appropriate cardiac imaging will allow one to narrow down the differential diagnoses and pursue appropriate therapy.

CARDIOMYOPATHIES

Dilated Cardiomyopathy

Dilated cardiomyopathies (see Chapter 65) share the common characteristics of an enlarged LV and/or RV cavity with systolic dysfunction. LV end-diastolic and end-systolic volumes, as well as LV end-diastolic dimensions and overall LV mass, are increased (with normal or thinned walls), and the overall ejection fraction is subnormal (see Tables 14-1, 14-2, and 14-3 for normal values). With persistence of the underlying condition, the left ventricle becomes less ellipsoid and more globular in shape, and the sphericity index decreases toward 1. The actual SV and cardiac output may remain preserved because of increased overall intraventricular volumes, as well as increased heart rate.

Dilated cardiomyopathies caused by processes such as viral, postpartum, genetic, and toxic-metabolic causes typically display diffuse LV hypokinesis; those caused by more focal processes such as sarcoidosis (or ischemic cardiomyopathy in patients with CAD) are more likely to have discrete areas of hypokinesis or akinesis. Ischemic heart disease is often accompanied by visible atherosclerotic plaque in the aortic root and other portions of the aorta. Very proximal CAD can actually be detected by examining the ostia of the coronary arteries with TEE. One clue to the presence of focal inflammatory processes is wall motion abnormalities that do not follow a coronary distribution and associated thickening secondary to edema. Approximately half of symptomatic patients with Chagas disease classically have an apical or inferobasal aneurysm, but more advanced cases

may feature global hypokinesis.³⁸ Takotsubo cardiomyopathy, which appears to be a stress- or neuroendocrine-mediated process, is unique in displaying a distinctive pattern of apical ballooning and basal hyperkinesis. Although the degree of dysfunction can be impressive in stress cardiomyopathy, remarkable and complete resolution can take place within days to weeks. A rarer “reverse” pattern of stress cardiomyopathy has also been described.³⁹ With sustained left-sided heart failure (and hence secondary pulmonary hypertension) or systemic causes of myocardial dysfunction, the right ventricle may also become dilated and hypokinetic, and enlargement of both atria—and hence four-chamber enlargement—is also common.

The degree of impairment in LV contractility is quantifiable by several means (see [Assessment of Cardiac Structure and Function](#), earlier). Historically, M-mode findings such as increased separation of the mitral E point from the interventricular septum, decreased mitral leaflet opening, and early closure of the aortic valve are known to correlate with poor cardiac output. The most widely used measure of systolic function is LVEF, which is considered subnormal if less than 55%. The total SV of the ventricle (reflected by VTI_{LVOT}) may be diminished, and tissue Doppler S' (systolic) excursion is diminished. Impairment of RV contractility may be assessed by parallel means, although it is more difficult to assess RV volume without the use of three-dimensional echocardiography. One easily obtainable measure of RV function is TAPSE, which reflects shortening in the long-axis dimension of RV myocardial fibers; a TAPSE of 11 mm or less is considered abnormal, and 14 mm or greater confers a worse prognosis in patients with dilated cardiomyopathy.

Functional MR with incomplete leaflet coaptation, which is due to multiple processes similar to that seen with ischemic cardiomyopathy, often accompanies and exacerbates dilated cardiomyopathy (see Fig. 14-32).³⁵ If the patient begins to experience right-sided heart failure because of left-sided heart failure (i.e., elevated LV end-diastolic pressure), the mitral and pulmonary venous inflow patterns will show diminution of systolic inflow in the pulmonary venous waveforms (reflecting elevated atrial pressure), and this may precede a rise in estimated pulmonary artery systolic pressure (as reflected by TR velocity).

Regardless of cause, a worse prognosis is associated with declining LVEF and elevated end-diastolic and end-systolic volume, increasing LV mass, the development of restrictive physiology by Doppler indices (see [Assessment of Diastolic Function](#), earlier), and the presence of right-sided heart failure, pulmonary hypertension, and severe TR.⁴⁰ If the LVEF is 35% or lower and the patient has an intraventricular conduction delay and clinical heart failure, CRT (see Chapters 26 and 36) may improve pump cardiac output, reverse the LV remodeling, and improve functional MR. Although many techniques for evaluating dyssynchrony by echocardiography have evolved and been tested (see [Echocardiography in Heart Failure](#), later), at present no single measure is accurate enough to predict the likelihood of response to CRT.⁴¹

Whereas chamber enlargement and systolic dysfunction are the prominent features in dilated cardiomyopathies, in *hypertrophic* and *restrictive cardiomyopathies* the ventricles are not dilated but diastolic filling of the ventricle is impaired. Declining systolic function typically appears only very late in the process. Both processes thicken the LV walls. Biatrial enlargement is frequent because the atria become the low-compliance reservoirs for cardiac inflow, particularly if atrial fibrillation is present.

Hypertrophic Cardiomyopathy

HCM is a primary, genetic disease of the sarcomere in which the ventricular walls are inappropriately hypertrophied and frequently asymmetrically thickened (see Chapter 66). This disorder should be distinguished from the more common focal upper septal hypertrophy, a discrete septal bulge that is frequently observed in older adults, is not usually associated with significant LVOT obstruction, and has a benign prognosis. In contrast, the most common forms of HCM of the obstructive type show the following echocardiographic features (Fig. 14-33): a small, hyperdynamic left ventricle with a thick sigmoid

FIGURE 14-33 HCM. A parasternal long-axis view (**left panel**) shows markedly increased septal wall thickness and systolic anterior motion of the mitral valve (**arrows**), also visualized in the apical four-chamber view (**right panel**). Note the sigmoid, banana-shaped septum. LA = left atrium; LV = left ventricle; VS = interventricular septum.

septum and/or banana-shaped cavity, asymmetric septal hypertrophy (septal thickness ≥ 1.6 times the thickness of the posterior wall), a relatively small LVOT, elevated flow velocity in the LVOT that peaks in late systole (when the LVOT is smallest), systolic anterior motion of the mitral valve, and often a significant amount of posteriorly directed MR. The LVOT gradient (ΔP) is calculated from PW Doppler LVOT peak velocity by the Bernoulli equation $\Delta P = 4(V_{LVOT})^2$. It reflects the degree of outflow obstruction caused by altered LV and mitral valve geometry. The combination of small LVOT area and motion of a relatively large, anteriorly positioned, slack mitral apparatus causes the mitral leaflets to be pushed into the LVOT in early systole by flow drag forces and, to a lesser extent, by suctioning via the LVOT gradient and Venturi effect. A maximum wall thickness greater than 30 mm or a resting LVOT gradient higher than 30 mm Hg is associated with increased risk for SCD and progression to New York Heart Association class III heart failure. The LVOT obstruction is highly dynamic, and in some individuals the LVOT obstruction and gradient can be significantly augmented by conditions that decrease preload and consequently also decrease LVOT size. Such maneuvers include the Valsalva maneuver, sudden standing, and exercise, all of which may be performed during echocardiographic evaluation of these patients.

There are other forms of HCM that may easily be recognized by echocardiography. In apical HCM, basal wall thickness may be normal, but the midventricular and apical portions are unusually thickened, and a midcavity gradient may exist; in more advanced cases, a distal apical aneurysmal area may develop (see Fig. 14-32C) and be associated with a higher incidence of arrhythmias, stroke, and SCD.⁴² In a minority (10% to 15%) of patients with HCM, systolic dysfunction ultimately develops and the heart progressively becomes more dilated and globally hypokinetic. For screening purposes it is important to keep in mind that some patients with HCM by genotype may have normal or only slightly increased wall thickness or may not manifest hypertrophy until late in adulthood.⁴³

Other Cardiomyopathies with Regional or Global Variations in Myocardial Composition

Left Ventricular Noncompaction. LV noncompaction is also thought to be a genetic abnormality and is characterized by abundant trabeculations and deep endothelial-lined recesses extending into the myocardial layer that have failed to compact. On echocardiography this confers a “spongy” appearance to the inner layer of the myocardium, whereas the outer layer has the normal “compacted” morphology (see Fig. 14-32D). Using color flow Doppler and/or echocardiographic contrast enhancement, blood perfusion between the intratrabecular recesses and the LV cavity can be demonstrated. With noncompaction

there is a spectrum of expression: the condition may affect the entire mid and apical ventricle or merely a portion of the apicolateral wall in less affected individuals, and the severity of trabeculation may vary. Because of both this variable expression and rising awareness of this entity, definitive imaging and clinical criteria for this disease continue to be refined. In general, a ratio of trabeculated to compacted layer thickness of greater than 2, as measured on short-axis views at the mid and apical levels, is considered to be consistent with noncompaction.⁴⁴ A more specific echocardiographic criterion may be a maximal systolic compacta thickness of less than 8 mm (in the segment with the most prominent recesses), which appears to better discriminate noncompaction from normal patients and those with pressure overload hypertrophy.⁴⁵

Arrhythmogenic Right Ventricular Dysplasia. Arrhythmogenic right ventricular dysplasia (ARVD) is distinct from the other nonischemic cardiomyopathies in affecting primarily the right ventricle (see Chapter 65). RV dilation (RVOT long-axis dimension >30 mm) is the most commonly associated abnormality, and RV global hypokinesis (FAC

$<32\%$) is present in most (see Fig. 14-32E). In some cases, segmental wall motion abnormalities, including thinning and aneurysms, may be present and are caused by fibrofatty infiltration. The inferoposterior wall of the RV inflow tract is the most frequent segment affected. RV trabecular derangement and subsequent TR secondary to annular dilation is common.⁴⁶ Echocardiography alone is insufficiently specific for the diagnosis of ARVD, and other causes of right-sided heart dilation and arrhythmia need to be excluded.

Restrictive Cardiomyopathies

Systemic diseases that can infiltrate the heart may lead to restrictive cardiomyopathies (see Chapter 65), with the most common being amyloidosis. Deposition of amyloid proteins in the heart causes a very distinct appearance on echocardiography, including increased LV and RV wall thickness in association with a very finely granular or “scintillating” echobright appearance of the myocardium and initially a preserved LVEF (see Fig. 14-32F). Advanced diastolic dysfunction is manifested both by Doppler indices and by strain imaging. Features that distinguish infiltrative cardiomyopathy from true LV hypertrophy include the concomitant presence of diffusely thickened valves, biatrial enlargement (“owl eyes” pattern), RV hypertrophy, pericardial effusion, and low voltage on the ECG. Although LVEF appears to be normal even in clinically affected individuals, there is often marked systolic dysfunction in the longitudinal axis as detected by both tissue Doppler and strain and strain rate imaging.⁴⁷

Apart from amyloid heart disease, echocardiography is frequently used to screen for cardiac involvement by other infiltrative diseases.⁴⁸ It may reveal abnormalities ranging from dilated to restrictive phenotypes, but no specific pattern is pathognomonic of any single cause. Heart failure develops in more than a third of patients with idiopathic or hereditary hemochromatosis, and they have echocardiograms revealing LV and LA dilation and global hypokinesis with normal LV wall thickness. A restrictive filling pattern may occur earlier than the manifestations of systolic heart failure. All these parameters of function have been shown to improve with iron removal therapy. Fabry disease is associated with accumulation of glycosphingolipid in the heart and a high incidence of cardiovascular signs and symptoms in addition to renal, dermatologic, and neurologic abnormalities. More than 80% of individuals with Fabry disease will display concentric hypertrophy, although concentric remodeling and asymmetric hypertrophy occur in a smaller proportion. The presence of LV hypertrophy is associated with lower alpha-galactosidase activity and more cardiovascular symptoms. Mitral leaflet thickening and significant MR are common, and focal or global LV systolic dysfunction occurs in a minority of patients.

Endomyocardial fibrosis, also termed Löffler endocarditis, is a rare restrictive cardiomyopathy frequently accompanied by peripheral eosinophilia, which may be idiopathic or associated with helminthic infection in the tropics. Eosinophilic endocarditis and infiltration of the myocardium lead to changes that can be striking on echocardiography. LV size and systolic function may be preserved, but a hallmark of this condition is the formation of prominent diffuse thrombi along the endocardium in one or both LV apices that may embolize and can grow large enough to actually obliterate the cavities. The ventricular cavities themselves are small with restrictive physiology because of the fibrotic process. Patients may display retracted and incompetent atrioventricular valves and marked biatrial enlargement. Because most patients are identified relatively late in the disease, the time course of development of the aforementioned changes is unclear.

Echocardiography in Heart Failure

Echocardiography is key in the diagnosis and management of patients with heart failure (see Chapters 25 and 27). Determination of LVEF is the primary method to distinguish heart failure with reduced ejection fraction (HFrEF) from HFpEF, with the latter generally being considered when the LVEF is 45% or greater. Echocardiography can help distinguish among the different types and narrow down the potential causes of heart failure from the main categories discussed earlier. Abnormalities in diastolic function are common in patients with heart failure and either reduced or preserved LVEF and may have prognostic implications. MR can occur in heart failure patients secondary to apical displacement of the papillary muscles, annular dilation, or both, and progressive ventricular dilation (see Chapter 63) can develop in patients with primary valvular MR. Increasing degrees of MR are associated with a poor outcome in patients with heart failure.

Assessment of Ventricular Synchrony

CRT (see Chapters 26 and 36) has been associated with a reduction in heart failure and death in patients with reduced LV function and a wide QRS complex in several outcomes trials.^{49,50} Use of CRT has also been associated with marked improvement in echocardiographic parameters such as end-diastolic and end-systolic volume, ejection fraction, RV function, and LA size.⁵¹ Most decisions regarding appropriateness for CRT are based on QRS width and bundle branch morphology on the ECG, as well as LV systolic function. The usefulness of echocardiographic assessment of ventricular synchrony in identifying patients who would benefit from CRT has been controversial. Several methods have been proposed for assessing synchrony. The simplest of these methods is determination of the time difference between peak contraction of the septum and posterior wall on M-mode echocardiography, in which dyssynchrony has been defined as a delay greater than 130 milliseconds. A similar method using time to peak contraction in opposing walls by strain imaging has also been proposed.⁵² More modern methods using DTI or speckle tracking assess the time to peak contraction in up to 12 segments and determine synchrony as the standard deviation of time to peak contraction from these multiple segments. In a large randomized outcomes trial, both ventricular synchrony and contractile function determined by echocardiography identified patients with an increased likelihood of benefit from CRT.⁵³ However, whether these techniques can or should be used to identify patients who will most benefit from CRT remains controversial, and a multicenter study of echocardiographic assessment in CRT failed to show a benefit for echocardiographic assessment of mechanical synchrony.⁵⁴

Assessment after Orthotopic Heart Transplantation. Echocardiography is used both to certify that cardiac structure and function are normal in potential heart donors and to monitor for rejection in cardiac transplant recipients (see Chapter 28). After uncomplicated orthotopic heart transplantation, the “normal” transplanted heart should display normal LV size, wall thickness, and systolic function, although RV size and function can be abnormal. In patients who have undergone the standard Shumway technique of transplantation,

the resultant atria are very enlarged and deformed because of the retained upper portion of the dilated native heart. In these patients the anastomosis between the donor and recipient heart may be visible as a thickened ridge that encircles the atria. The ridge is not infrequently mistaken for thrombus by inexperienced observers. The newer alternative surgical methods retain no recipient myocardium (in the procedure of total atrioventricular transplantation) or only a limited cuff of LA wall with pulmonary vein ostia (in the bicaval technique) and thus preserve more normal atrial architecture with relatively inapparent suture lines. A “normal” transplanted heart often has slight paradoxical septal motion—anterior motion of the septum in systole and a slight decrease in septal systolic thickening—that persists in the postoperative state. Over time, in part because of distortions in atrial geometry, supraventricular arrhythmias, and repeated endomyocardial biopsies causing incidental damage to the tricuspid valve, significant TR and MR, as well as atrial thrombi, may develop in the allograft heart.

Cardiac allograft dysfunction may result from many reasons: acute rejection, coronary artery vasculopathy, myocardial fibrosis, acute myocarditis from opportunistic infections, or tachycardia-mediated cardiomyopathy. Cardiac ultrasound may detect the “downstream” effects of these pathologic mechanisms. Acute cellular rejection, which results in edema and interstitial infiltrates in the myocardium, has been shown to cause detectable increases in LV wall thickness and mass, systolic dysfunction, and Doppler indices of elevated LA pressure and restrictive physiology (increased E wave velocity, decreased IVRT and mitral deceleration time), but these changes are of insufficient sensitivity and specificity to rely on for routine clinical screening. Speckle tracking, in particular, LV torsion, appears to have higher predictive accuracy (92%) and thus may have a potential role in serial monitoring for rejection,⁵⁵ but wider validation and outcome-based studies are required. For now the gold standard for detecting acute rejection remains endomyocardial biopsy, but echocardiography has an appropriate supplementary role in monitoring for rejection and other complications following transplantation.

For detecting cardiac allograft vasculopathy, coronary IVUS is the gold standard, although coronary angiography is used more routinely for practical reasons. Among noninvasive imaging techniques, echocardiography is the most widely investigated and used. The presence of depressed LVEF or focal wall motion abnormalities on a *resting* echocardiogram is relatively specific (>80% in multiple studies) for allograft vasculopathy but has poor (<50%) sensitivity. Some centers use dobutamine stress echocardiography (DSE), which is preferred over exercise stress echocardiography because denervation of the allografted heart blunts the heart rate response to exercise. Meta-analysis of the published data (small studies with <110 patients) on the accuracy of DSE indicates a mean specificity of 88% and a sensitivity of 72%. The use of longitudinal strain rate imaging or myocardial echocardiographic contrast enhancement with DSE may increase the sensitivity, but again, more validation is needed. For prognostic purposes, however, normal findings on DSE have been shown to have a high negative predictive value for adverse cardiac events (0.6% incidence) over short-term follow-up. Conversely, worsening findings on serial DSE confer increased risk in comparison to stable findings. Hence currently, DSE (as well as SPECT) is considered by the International Society of Heart and Lung Transplantation⁵⁶ as possibly being useful (class IIa, level of evidence B) in transplant recipients who are unable to undergo invasive evaluation. Some centers use DSE to minimize exposure of transplant patients to coronary angiography, although currently no noninvasive imaging modality is sufficiently accurate to supplant it.

Assessment of Left Ventricular Assist Devices. The advent and increasing use of a variety of VADs for both bridge and destination therapy (see Chapter 29) have mandated that echocardiography play an integral role in assisting in the optimal selection of patients for left and right VADs, implantation, optimization, and troubleshooting. Here we address the principles for the more widely used HeartMate devices, which are now continuous-flow pumps.

All LV assist devices (LVADs) work by unloading the ventricle (i.e., removing some or all of the inflow and pumping it to the aorta). Echocardiography is useful for evaluation of the patient *preoperatively* for VAD implantation and for evaluating LV as well as RV function.^{57,58} If RV failure is too severe, as may be indicated by a number of parameters such as RV FAC, TAPSE, and the RV Tei index (see the section *Right Ventricular Evaluation*), there will be insufficient preload to fill the VAD and left ventricle. The incidence of right-sided heart failure is 20% to 30% in patients implanted with an isolated LVAD, and a preoperative RV FAC lower than 20% is associated with RV failure on activation of the LVAD device. In addition, echocardiography (TTE and/

or TEE) can identify aortic insufficiency, intracardiac shunting, thrombi in the LV or LA appendage, or structural problems with inflow and outflow site cannulation such as excessive necrosis or atherosclerotic plaque, which are detrimental to proper LVAD function. *Intraoperatively*, TEE is used to ensure proper LV apical coring, de-airing, and cannula position and to reassess RV function on initial start-up of the LVAD. Extreme RV failure may mandate placement of an RV assist device (RVAD) as well.

Postoperatively, the echocardiogram may be used to identify causes of LVAD dysfunction and fine-tune its operation. When the LVAD is working properly, the ventricle should be “decompressed,” that is, smaller than its original dilated size with the interventricular septum in a neutral position. The aortic valve in a completely decompressed heart stays completely closed throughout the cardiac cycle. Thickening and fusion of the aortic valve may occur over time, particularly in nonpulsatile LVADs; growing experience with these continuous-flow devices supports a rationale for adjusting flow settings to permit at least occasional opening of the aortic valve (i.e., on a 1:3 cyclical ratio) to avoid this valvulopathy and associated aortic regurgitation. Enlargement of the left ventricle, distention of the interventricular septum rightward, and rising estimated pulmonary artery systolic pressure are signals of a relatively underfunctioning device that may be due to an inadequate pump rate, worsening ventricular function, aortic regurgitation, volume overload, or systemic factors (e.g., sepsis). If the left ventricle appears small and the interventricular septum is shifted leftward, this indicates inadequate preload to the ventricle, and factors such as RV failure, pulmonary embolus, tamponade, hypovolemia (e.g., bleeding), or obstruction of the inflow cannula should be sought. Obstruction may be caused by LV thrombus, a papillary muscle or chord, or bending or slippage of the cannular or outflow graft. Such abnormalities may be demonstrated by two-dimensional echocardiography or by increased velocities and turbulence seen with Doppler evaluation at the cannula/graft orifices. The LVAD inflow cannula should be visible at the apex, and the outflow graft/cannula can occasionally be detected by angling into the ascending aorta with a right parasternal view. Occasionally, positional kinks in the LVAD cannulas or the aortic outflow graft, which tend to occur in smaller patients, can be demonstrated by scanning the patient in the supine, sitting, and standing positions.

There are also *percutaneously implanted VADs* (PVADs) that provide partial support for the left ventricle. Echocardiography can confirm that the cannulas are in the appropriate position across the interatrial septum (in the case of the TandemHeart PVAD, CardiacAssist, Pittsburgh, Pa) or the aortic valve/LVOT (for the Impella).

Lung Ultrasound in Heart Failure

Although not widely used, lung ultrasound is a novel technique that can provide semiquantitative assessment of lung fluid in patients with heart failure. Even though pleural effusions have long been associated with heart failure and can be detected by ultrasound with high sensitivity, images from aerated lung tissue have generally been discounted because of the artifacts that arise from ultrasound pulses traversing lung tissue. Nevertheless, vertical artifacts arising from the pleural line on lung ultrasonography (so-called B lines) represent markers of increased extravascular lung water.⁵⁹ Although B lines can also be seen in other pathologic processes affecting the lung interstitium, such as pulmonary fibrosis, acute respiratory distress syndrome, or pulmonary contusions, detection of such lines has been found to be useful in the assessment of dyspneic patients in the emergency department. The presence of multiple bilateral B lines (**Fig. e14-9**) permits differentiation of dyspneic patients with acute decompensated heart failure from those with noncardiogenic dyspnea with higher sensitivity than possible with chest radiography.⁶⁰ Sonographic B lines have also been found to resolve within hours to days of treatment of acute decompensated heart failure and correlate with natriuretic peptides in this population,⁶¹ as well as with pulmonary artery diastolic pressure.⁶² The prognostic usefulness of these artifacts in acute and chronic heart failure is currently under investigation.

STRESS ECHOCARDIOGRAPHY

Stress echocardiography is a well-validated tool for the evaluation of ischemia. In particular, it is an appropriate first-line test in patients

who have baseline abnormalities on the ECG that preclude interpretation of exercise ECGs, and it is both time- and cost-efficient. The accuracy of stress echocardiography is similar to that of stress radionuclide perfusion imaging (**see Chapter 16**). From meta-analyses, as well as from comparisons of the accuracy of stress echocardiography and nuclear imaging in the same patient population, the sensitivity of stress echocardiography for significant CAD (generally defined as >50% coronary artery stenosis by angiography) averages approximately 88% (range, 76% to 94%), and its specificity is 83%.⁶³ The specificity of stress echocardiography appears to be higher than that of nuclear imaging for left main and triple-vessel CAD. As with other tests, stress echocardiography is best used for diagnosis or to identify the extent, severity, and location of ischemia in patients with an intermediate pretest probability of disease.

The Stress Echocardiographic Protocol. In the standard stress protocol, baseline images are obtained at rest, before the patient exercises on either a treadmill or stationary bicycle. The same Bruce protocol used for nonimaging (ECG only) exercise stress tests is standard (**see Chapter 13**), with echocardiographic imaging performed at rest and during immediate recovery as close to the peak exercise time as possible. If a stationary (upright or supine) bicycle is used, the workload is increased by 25 W every 2 or 3 minutes, and echocardiographic images can be obtained on the cycle precisely at the time of peak stress. Patients who cannot exercise can undergo pharmacologic stress with a graded dobutamine infusion of up to 40 µg/kg/min (and added atropine, if necessary, to achieve the target heart rate), which increases the heart rate and myocardial contractility. This method, although less physiologic than exercise, produces a smaller rise in blood pressure and also allows imaging exactly at time of peak stress. Vasodilator stress with dipyridamole and pacing stress—via a preexisting permanent pacemaker or a transesophageal pacing catheter—are also possible but less widely used. The test endpoint is completed by exercise-limiting symptoms or completion of the protocol (reaching at least 85% of the age-predicted maximal heart rate).

Absolute indications to terminate the test early include moderate to severe angina, ST-segment elevation, sustained ventricular tachycardia, near syncope or signs of poor perfusion, a drop in systolic blood pressure of more than 10 mm Hg from baseline when accompanied by any other evidence of ischemia, and patient request to stop (intolerable symptoms). Relative indications to stop early include a hypertensive response (systolic blood pressure >250 mm Hg and/or diastolic blood pressure >115 mm Hg).⁶³ The risks associated with exercise echocardiography or DSE are very low. In the largest survey to date, the overall rate of life-threatening events was 1 per every 1000 examinations (0.015% for exercise and 0.18% for dobutamine).⁶⁴ The most frequent complications were acute MI or ventricular tachycardia or fibrillation.

If a previous echocardiogram has not been performed, a brief survey of the ventricular chambers, valves, and aortic root should be performed to screen for significant pathology or contraindications to stress and to ensure adequate image quality (usually obtainable in at least 90% of patients with harmonic imaging). If endocardial resolution is poor in two or more segments, intravenous echocardiographic contrast enhancement should be used to improve accuracy.³² Images of the left ventricle are then obtained in the parasternal long, parasternal short, and apical windows at rest and then with stress. Side-by-side comparison of the baseline versus stress digitized images, which are gated by the ECG and synchronized in systole, allows quantification of overall LV size and systolic function, as well as identification of regional wall motion abnormalities. The standard 17-segment ASE model is used as the guide for grading function in each segment as normal, hyperkinetic, hypokinetic, akinetic, or dyskinetic at rest and with stress or increasing doses of dobutamine. A normal ventricle has normal size and wall thickness and an ejection fraction of 55% or higher with no focal wall motion abnormalities (WMSI = 1.0); with stress the ventricle should become hypercontractile and the cavity size should shrink. The presence of baseline wall motion abnormalities that remain “fixed” (unchanged) with stress is indicative of a previous infarct. The development of a new or worsening wall motion abnormality indicates a flow-limiting stenosis in the coronary artery supplying the abnormal segment or segments (**Fig. 14-34**). A large ischemic territory (i.e., left main or multivessel disease) will be manifested as diminished global LVEF and chamber dilation with stress.

FIGURE e14-9 Sonographic B lines from lung ultrasound. **Left,** Multiple sonographic B lines or “ultrasound lung comets.” **Right,** Normal lung on ultrasound examination.

FIGURE 14-34 Stress echocardiography showing evidence of ischemia in the LAD distribution. Resting and stress echocardiograms in the apical four-chamber (A4) and apical two-chamber (A2) views reveal new severe mid to distal anteroseptal, apical, and distal inferior LV hypokinesis (arrows). This patient was found to have greater than 90% mid-LAD stenosis on cardiac catheterization.

Limitations of Stress Echocardiography

When compared with the gold standard of coronary angiography, the results of stress echocardiography can be discrepant.⁶⁵ When false-negative results occur, primary causes include a suboptimal level of stress (because of inadequate exercise capacity or beta blocker use), limited image quality, a small area of ischemia (particularly for single-vessel or left circumflex disease), or preexisting conditions such as marked LV hypertrophy or a hyperdynamic state. False-positive results may also occur, particularly when the pretest probability is low. Diagnosis of wall motion abnormalities is particularly challenging in patients with left bundle branch block or septal dyssynchrony (as a result of pacing or the postoperative state). Because exercise can exaggerate the abnormal septal motion in these patients and thereby obfuscate interpretation, DSE is recommended. A focus on wall thickening rather than on endocardial excursion may also be helpful in such situations. Other conditions that can cause nonspecific or nondiagnostic findings include the presence of preexisting wall motion abnormalities that tether adjacent segments, severe hypertension, HCM, and other cardiomyopathies in which myocardial perfusion reserve is diminished as a result of microvascular disease.³²

Risk Stratification with Stress Echocardiography

Numerous studies have demonstrated that in patients who complete normal exercise or pharmacologic stress echocardiograms (reaching good exercise capacity and the target heart rate), the risk for cardiac events is very low and at or close to that of a “normal” population (<1% per year for exercise and <2% per year for pharmacologic tests). In patients with suspected or known CAD, both the extent of resting wall motion abnormalities and the extent of ischemia—specifically quantified by the change in WMSI, four or more LV wall segments affected, and/or no change or decrease in exercise LVEF—correlate with a fourfold or greater increased risk for cardiac death or MI.³²

Assessment of Viability

DSE can also be used to quantify viability (contractile reserve) and hence functional recovery after reperfusion,⁶⁶ although its overall sensitivity appears to be lower than that of nuclear and CMR studies. A biphasic response—in which improvement in wall thickening occurs at low-dose dobutamine but then deteriorates with high-dose dobutamine—is the most specific sign. However, any improvement in wall motion abnormality by at least one grade in two or more segments during stress is likely to signify viability (either stunned or hibernating myocardium).

Coronary Flow Reserve and Perfusion

It is feasible to assess coronary flow and flow reserve (see [Chapter 49](#)), most reliably in the LAD territory, by using Doppler TTE and vasodilators (adenosine or dipyridamole) to provide additional prognostic information. Coronary flow reserve reduced to less than 1.9 to 2.0 in the LAD territory correlates with greater than 70% angiographic stenosis and is a predictor of future adverse cardiac events. Microperfusion to the myocardium at rest and with stress echocardiography may also be demonstrated with the use of intravenous echocardiographic contrast enhancement on two- and three-dimensional images (see also [Contrast Echocardiography](#)). In laboratories with expertise, both techniques of assessing myocardial perfusion appear to have acceptable agreement when compared with angiography and nuclear stress tests. However, technical challenges and a learning curve presently exist, which has currently limited widespread adoption of these methods.⁶⁵

Stress echocardiography is a very versatile modality and is used to assess factors beyond LV systolic function, particularly in patients who are dyspneic for unclear reasons. Valvular disease, diastolic function, pulmonary hypertension, and hemodynamics may all be assessed under stress conditions.

Stress Echocardiography in Valvular Heart Disease

Resting echocardiography may lead to conflicting interpretations of the degree of aortic stenosis in patients with very calcified valves and low LVEF because leaflet excursion and both the LVOT and aortic gradients are diminished simply by low forward flow (see [Chapter 63](#)). In patients with “low-gradient, low-output aortic stenosis” and LV dysfunction (defined as a calculated aortic valve area by Doppler <1.0 cm², mean transaortic gradient <30 to 40 mm Hg, and LVEF ≤40%), DSE can be used to assess both the true severity of aortic stenosis and the amount of LV contractile reserve (see also the section Aortic Stenosis). In this test, dobutamine is infused in graded doses from 5 to 20 µg/kg/min, typically for longer stages than used for ischemia testing, and spectral Doppler of the LVOT and CW Doppler across the aortic valve are performed. SV is calculated from VTI_{LVOT}. An increase of 20% or greater in SV is indicative of significant contractile reserve. The test will be uninterpretable if no augmentation of LV function takes place (no contractile reserve). Aortic valve area is calculated at both baseline and with dobutamine; in true aortic stenosis the ratio of aortic and LVOT velocity will increase, whereas in “pseudosevere” or “functional” aortic stenosis, the LVOT and aortic gradients change relatively little, and the calculated valve area remains the same or increases as the leaflets open more. Patients with true severe aortic stenosis generally benefit from aortic valve replacement, but if contractile reserve is absent and/or concomitant CAD is present, operative mortality is high.⁶⁷

A subset of patients—often females with small ventricles—with advanced aortic stenosis have been described who have low-gradient/low-flow states despite preserved LVEF (see [Chapter 63](#)). On DSE these patients usually appear to have low aortic valve areas consistent with true severe aortic stenosis even with stress, but only modest gradients despite preserved LVEF. These patients have a poor prognosis, which is improved by aortic valve replacement. The explanation appears to be pronounced LV concentric remodeling and myocardial fibrosis that results in severe restrictive physiology and low SV (not reflected by the LVEF because of small total chamber size). If this state is suspected, it may be useful to further elucidate the degree of aortic and restrictive pathophysiology by indexing the valve area to body size, measuring global longitudinal and midwall strain, and calculating a newer measure termed valvuloarterial impedance ($Z_{va} = [\text{Systolic blood pressure} + \text{Peak AV gradient}]/\text{SV}$ indexed to body surface area). The aortic valve may also be evaluated directly with CT for aortic valve calcium scores.⁶⁷

Patients with rheumatic or calcific mitral stenosis may have severe exertional symptoms despite relatively modest gradients on the resting echocardiogram. Conversely, sedentary patients with severe mitral stenosis may be relatively asymptomatic because they are inactive. Valve gradients are notoriously dependent on the flow rate and heart rate. Stress echocardiography can define the true exercise

FIGURE 14-35 Stress echocardiography with evidence of ischemia in the RCA territory and acute ischemic MR. Resting and stress echocardiograms in the apical two-chamber (A2) and apical four-chamber (A4) views with color Doppler reveal new stress-induced inferior hypokinesis (arrows) in the area containing the posteromedial papillary muscle and increased MR. This patient was found to have 90% stenoses of the RCA and left circumflex artery on cardiac catheterization.

capacity and quantitate the degree of valvular stenosis and regurgitation. A rise in the mean transmitral pressure gradient of higher than 15 mm Hg or an increase in calculated pulmonary artery systolic pressure of greater than 60 mm Hg is correlated with significant mitral stenosis, and such patients should be considered for valvotomy (if the cause is rheumatic and there is no more than mild MR) or mitral valve replacement (see Chapter 63).³² Mitral valve surgery should also be considered if severe MR occurs with stress. If symptoms and pulmonary artery systolic pressure increase markedly while transmitral gradients remain low, however, a pulmonary cause should be sought.

In patients with MR, stress echocardiography may be instrumental in revealing acute reversible ischemic MR caused by inferior wall ischemia (Fig. 14-35). This would characteristically be associated with stress-induced inferior wall motion abnormalities and improvement in both abnormalities during recovery. In chronic severe MR, even if the LVEF is preserved, demonstration of a rise in pulmonary artery systolic pressure to higher than 60 mm Hg with exercise and reduced LV contractile reserve are reasonable indications for mitral valve surgery.³²

Stress echocardiography may be tailored in other conditions. In patients with HCM, exercise can bring out latent gradients and is also used to both monitor response to therapy and assess symptoms such as syncope (see Chapter 66).

In conjunction with cardiopulmonary testing, stress echocardiography may aid in rooting out the cause of dyspnea and fatigue and in identifying diastolic dysfunction. Delayed diastolic relaxation, as measured by strain and strain rate imaging, may also be a more sensitive and persistent indicator of exercise-induced ischemia than wall thickening is. With the advent of real-time three- and four-dimensional imaging, automatic endocardial border tracking, and volumetric imaging, there is now the capability to capture images of LV systolic and diastolic function simultaneously at peak exercise, thereby potentially improving the sensitivity, accuracy, and reproducibility of this test for ischemia.

VALVULAR HEART DISEASE (see Chapter 63)

Mitral Valve

Mitral Valve Anatomy. The mitral valve apparatus is a complex structure consisting of two leaflets attached to the left atrium via the

mitral annulus and to the left ventricle through the mitral chordae and papillary muscles. The posterior leaflet is divided naturally into three scallops termed P1, P2, and P3 (using the Carpentier nomenclature), with P1 being lateral and P3 being medial. Opposing scallops of the anterior leaflet are termed A1, A2, and A3. Localization of pathology to specific scallops is important, particularly in surgical decision making for degenerative MR. The annulus is a nonplanar saddle-shaped structure, with its highest points seen on the parasternal long-axis view and its nadir seen in the apical four-chamber view. The chords consist of a complex arcade of primary or first-order and secondary or second-order chordae radiating from both papillary muscles, with the former being inserted along free margin of both leaflets and the latter serving as strut supports to the leaflet undersurfaces. Tertiary or third-order chordae arise from the ventricular wall and insert into the base of the posterior leaflet only (Figs. 14-36 and e14-10).

Although it is possible to identify each of the scallops with two-dimensional TTE on the parasternal short-axis view at the level of the mitral valve, it may be challenging to identify the scallops in the other views. Consequently, TEE plays a particularly important role in assessment of the mitral valve. Three-dimensional TEE has rapidly become an essential tool because of its ability to provide images that replicate the surgeon's view of the valve (Fig. 14-36), as well as improved methods for assessing mitral pathophysiology in a variety of disease states. Congenital anomalies of the mitral valve are unusual, but those that might be newly diagnosed in adulthood include double-orifice mitral valve and parachute mitral valve.

Mitral Stenosis

Echocardiographic Features

The commissural fusion, chordal thickening and fusion, and leaflet thickening and calcification that develop in patients with rheumatic mitral stenosis result in narrowing of the mitral orifice, classically with a fish-mouth configuration (see Fig. 63-21). Other pathognomonic echocardiographic features of rheumatic mitral disease are best appreciated on the parasternal long- and short-axis views and apical views. Commissural fusion results in restricted diastolic excursion of the tips of the leaflets, with relatively preserved mobility of the belly of the leaflet, particularly in early or milder forms of the disease. The result is a pattern of opening in which excursion of the midsection of the leaflet exceeds that of the leaflet tips. This pattern, also encountered in rheumatic tricuspid stenosis and congenital anomalies of the aortic valve (discussed later), is termed *doming*. In rheumatic mitral disease, anterior leaflet doming is more readily appreciated because the posterior leaflet is shorter and tends to become immobilized early in the rheumatic process (Fig. 14-37). Leaflet and chordal thickening with or without calcification is also seen. Despite the fact that degenerative mitral annular calcification is a common anomaly, it infrequently causes mitral stenosis unless very severe.

Quantification of Severity

The normal mitral valve area (MVA) is 4 to 5 cm². Direct planimetry of the orifice area from a parasternal short-axis view was first validated in the pre-Doppler era. It relies on meticulous positioning of the imaging plane at the level of the flow-limiting orifice; misleadingly larger-appearing "orifices" will be captured if the plane used is at the level of more mobile leaflet segments. It is equally important for the gain to be set at the lowest possible setting that will provide a complete orifice. Overgained images will also underestimate the true valve area. Three-dimensional echocardiography has proved to be a valuable tool because it provides a robust means of identifying the valve orifice (Fig. 14-38).

Determination of the mean gradient is the simplest Doppler method for assessing the severity of mitral stenosis. Given the degree to which gradients are influenced by flow rate, it is important to report the heart rate at which the gradient was determined and to be aware of the impact of concomitant MR, which can increase transmitral flow. Abnormalities that increase LV pressure independent of transmitral flow, such as reduced LV compliance and aortic regurgitation, can attenuate the transmitral gradient and result in underestimation of the severity of mitral stenosis.

FIGURE e14-10 Normal mitral valve anatomy. Ao = aorta; LV = left ventricle; PA = pulmonary artery; RA = right atrium; RV = right ventricle; TV = tricuspid valve. (Modified from Bulwer BE, Rivero JM [eds]: *Echocardiography Pocket Guide: The Transthoracic Examination*. Burlington, Mass, Jones & Bartlett Learning, 2011, 2013, p 132. Reprinted with permission.)

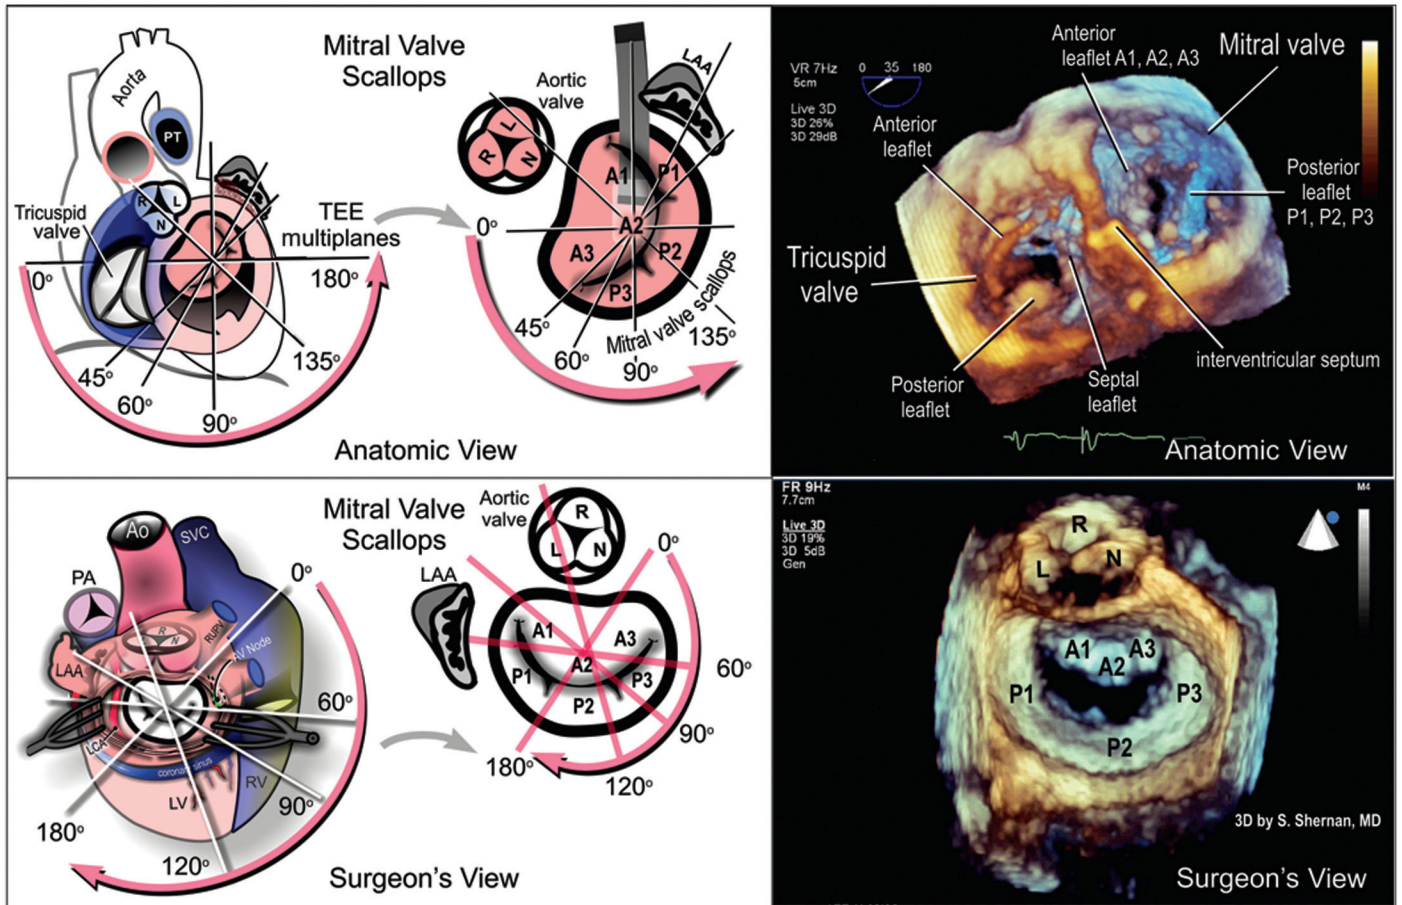

FIGURE 14-36 Mitral valve anatomy from TEE. **Left**, Two-dimensional approach involving adjustment of probe position (flexion, retroflexion, medial and lateral rotation), as well as the omni orientation (degrees), to image all scallops. **Right**, Three-dimensional echocardiographic appearance of the valve with the leaflet scallops labeled. The right (R), left (L), and non (N) coronary cusps of the aortic valve are shown. Ao = aorta; AV = aortic valve; LAA = left atrial appendage; LCA = left coronary artery; PA = pulmonary artery; RUPV = right upper pulmonary vein.

FIGURE 14-37 Rheumatic mitral stenosis. Parasternal long-axis view (diastolic frame) of a rheumatic mitral valve. Diastolic doming of the anterior mitral leaflet (arrow) is present, as well as a fixed posterior leaflet. LA = left atrium.

Doppler echocardiography also provides alternative methods to planimetry for determining MVA. The most widely used approach is the pressure half-time method, which relies on the rate at which LA and LV pressures equalize. Using a simplified derivation of a catheterization laboratory-validated method, MVA is calculated as 220 divided by pressure half-time, with 220 being an empirically derived constant and pressure half-time being the time that it takes the initial transvalvular gradient to fall to half its initial value. This calculation can rapidly be done online with the basic analysis packages available on echocardiographic machines (**Fig. 14-39**). The pressure half-time method should not be used in the immediate postvalvuloplasty setting because acute changes in the LA-LV compliance relationship and in the initial transmitral gradient may have occurred. It may also be invalid in the setting of significant aortic regurgitation and reduced LV compliance, each of which will result in overestimation of valve area. Additionally, the pressure half-time may be indeterminate when the mitral inflow Doppler spectrum has a biphasic contour. Finally, this method has not been validated for other causes of mitral stenosis such as mitral annular calcification or for prosthetic valves.

An alternative method is the proximal isovelocity surface area (PISA) approach (**Fig. 14-40**), in which $MVA = 2(\pi r^2)(V_{aliasing}) / (\text{Peak } V_{mitral}) \times \alpha / 180$, where α is the angle formed by the doming cusps, or a simplification of this equation in which α is assumed to be 100 degrees. A continuity-based method has also been proposed whereby $MVA = \pi(D_{LVOT}/2)^2(VTI_{LVOT}/VTI_{MV})$ where D is the diameter of the LVOT measured on the parasternal long-axis view. As with other forms of valvular heart disease, an approach that integrates imaging and Doppler findings will optimize assessment of mitral stenotic severity.⁶⁸

FIGURE 14-38 Approaches to planimetry of the MVA in rheumatic mitral stenosis. **Top panel**, Planimetry of two-dimensional parasternal short-axis images. **Middle panel**, three-dimensional TEE view from the perspective of the left ventricle showing the stenotic orifice. This can be directly planimeted or an estimate of area can be made by using a superimposable calibrated grid. **Lower panel**, Multiplanar reconstruction of three-dimensional TEE volumes can ensure that a short-axis view precisely at the level of the limiting orifice is available for planimetry.

FIGURE 14-39 Planimetry of the CW mitral stenotic spectrum (dotted line) provides the mean transvalvular gradient, whereas assessment of the rate at which the gradient between the left atrium and left ventricle falls (marked by the two X's) can be used to calculate valve area from the pressure half-time method ($P_{1/2}t$). MV = mitral valve; MVA = MV area; PG = pressure gradient.

Patient Selection for Balloon Valvuloplasty

In patients with severe mitral stenosis in whom transcatheter intervention is planned, the Wilkins echocardiographic scoring system (Table 14-10) is useful in determining the likelihood of overall procedural success, and the less widely used Padial scoring system is useful in predicting freedom from severe MR, with scores higher than 8 and 10 or higher, respectively, being predictors of poorer outcomes. It is also important to determine the amount of associated MR on echocardiography because percutaneous balloon mitral valvotomy

will usually increase the severity of regurgitation by at least one grade.

Mitral Regurgitation

Causes of Mitral Regurgitation

Minor leakage of the mitral valve is a common physiologic finding. There are many causes of pathologic regurgitation, and echocardiography should be used not only to simply diagnose and quantify MR but also to determine the underlying functional disturbance and, when possible, to identify the disease that has caused the disturbance (see Chapter 63). Carpentier proposed a useful classification system based on the pathophysiology of MR that lends itself to an echocardiographic approach. In type I, leaflet motion is normal and the most common abnormalities are leaflet perforation, alteration in coaptation because of bulky vegetation, or annular dilation secondary to chronic atrial fibrillation. In type II, at least one leaflet overrides the most superior plane of the annulus, that is, mitral prolapse or flail on the basis of either intrinsic valvular abnormality or rupture of either the chordae or papillary muscles. In type III A, leaflet motion is restricted during both systole and diastole, most commonly because of rheumatic disease, whereas in type III B, motion is limited in systole because of pathologic tethering on the basis of LV systolic dysfunction and

remodeling, so-called functional MR (Fig. 14-41).

Degenerative Mitral Regurgitation

Mitral prolapse or flail that is attributable to primary leaflet and/or chordal pathology is termed degenerative MR. Echocardiography is the gold standard for the diagnosis of mitral prolapse or flail. The two are distinguished by the fact that in flail, the unsupported free edge of the mitral leaflet extends into the left atrium because of loss of chordal support whereas in prolapse, the free edge remains tethered by chords and the leaflet billows pathologically into the left atrium. The diagnosis of prolapse is made from the parasternal long-axis view when any part of the leaflet extends 2 mm above a line drawn from the insertion of the anterior and posterior leaflets (Fig. 14-42). This line represents the most superior aspect of the saddle-shaped annulus. In the apical four- and two-chamber views, some extension of leaflet tissue above the annular boundaries is a normal variant and in most cases is not diagnostic of prolapse, although these views may demonstrate the classic billowing motion of a truly prolapsing mitral valve. It may be difficult to differentiate between prolapse and flail with TTE alone, but TEE can assist in making the correct diagnosis.

The anatomic substrate for degenerative MR spans the spectrum from diffuse myxomatous change (Barlow) to localized abnormalities characterized as fibroelastic deficiency. Three-dimensional echocardiographic assessment of the extent of billowing has been reported to be useful in characterizing the nature of the pathology but, more importantly, has assumed a key role in determining precisely which scallop or scallops are prolapsing or flail. This information is essential in predicting the likelihood of successful repair. There is a high probability of successful repair for isolated P2 pathology, which is fortunately the most common pattern. Next in frequency and ease of repair is A2 disease, followed by abnormalities in the medial and lateral scallops. Three-dimensional TEE is also helpful in identifying involvement of multiple scallops or unexpected associated anomalies such as localized mitral valve clefts. In the absence

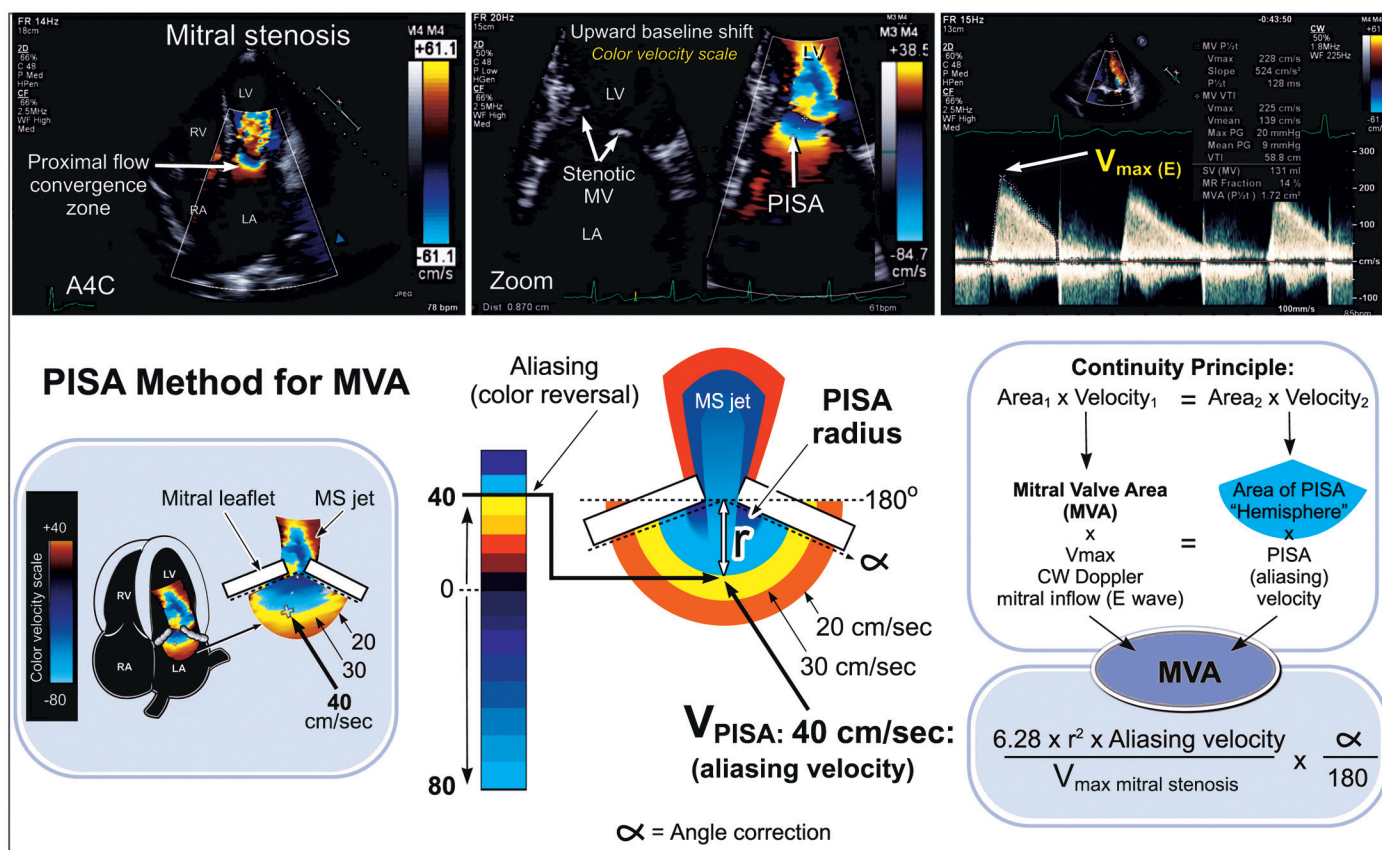

FIGURE 14-40 PISA method for calculation of MVA. In patients with mitral stenosis (MS), flow acceleration proximal to the stenotic orifice will result in a flow convergence zone that is characterized by color aliasing and a PISA shell (**upper left**). The hemisphericity and definition of the PISA shell and thus the accuracy of the PISA radius measurement can be improved by shifting the baseline in the direction of flow (**upper middle**). In the schematic images in the **lower left** and **middle panels**, the aliasing velocity is 40 cm/sec. Application of the continuity equation allows MVA to be calculated as $MVA = [2(\pi r^2)(V_{\text{aliasing}})] / (\text{Peak } V_{\text{mitral}}) \times \alpha / 180$. The angle correction is most important when the aliasing velocity is less than 40 cm/sec and is used to correct for deviation of the shell from hemisphericity. A4C = apical four chamber; LA = left atrium; LV = left ventricular; RA = right atrium; RV = right ventricle.

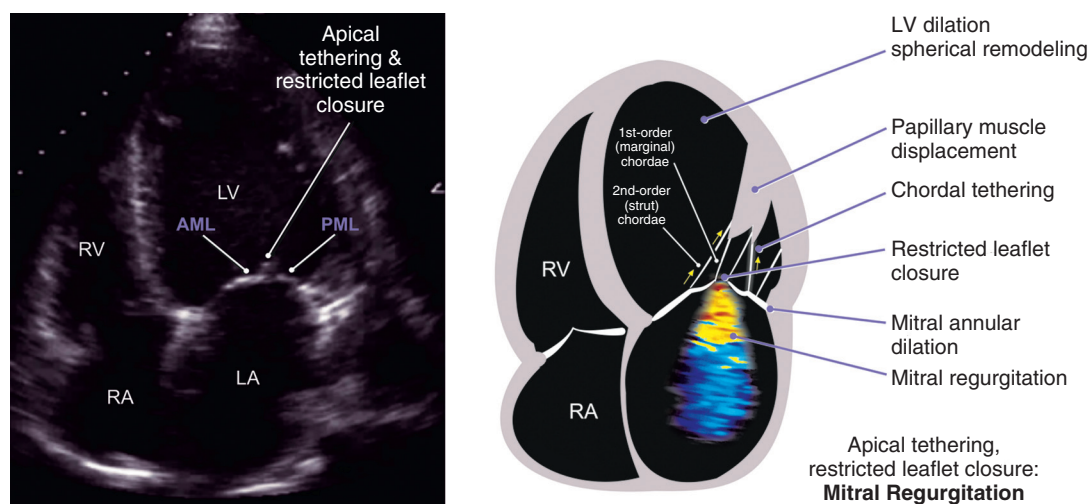

FIGURE 14-41 Functional/ischemic MR. Mitral tethering forces are increased because of both annular dilation and papillary muscle traction, which occur as a result of LV remodeling. Closing forces are reduced because of impaired LV systolic function. The end result is apical displacement of leaflet coaptation, which creates a "hockey stick" configuration of one or both leaflets as shown in the apical four-chamber view on the left. AML = anterior mitral leaflet; LA = left atrium; LV = left ventricle; PML = posterior mitral leaflet; RA = right atrium; RV = right ventricle.

TABLE 14-10 Wilkins Scoring System for Mitral Valvuloplasty

GRADE	LEAFLET MOBILITY	VALVE THICKENING	CALCIFICATION	SUBVALVULAR THICKENING
1	Highly mobile	Minimal thickening	Single area of brightness	Minimal chordal thickening
2	Reduced mobility	Thickened tips	Scattered areas at leaflet margins	Chordal thickening up to $\frac{1}{3}$
3	Basal leaflet motion only	Entire leaflet thickened	Brightness extends to mid leaflets	Distal third of chordae thickened
4	Minimal motion	Marked leaflet thickening	Extensive leaflet brightness	Extensive thickening to papillary muscles

A desirable score is 8 or lower.

FIGURE 14-42 Degenerative MR. **Left**, Parasternal long-axis view showing bileaflet prolapse as evidenced by billowing of both leaflets (arrows) above the plane defined by the insertion of the anterior and posterior leaflets (line). **Right**, Three-dimensional transesophageal image of the mitral valve from a left atrial perspective. There is a large flail segment of the anterior mitral leaflet (AML). Arrows point to ruptured chordae. AV = aortic valve; LA = left atrium; PML = posterior mitral leaflet.

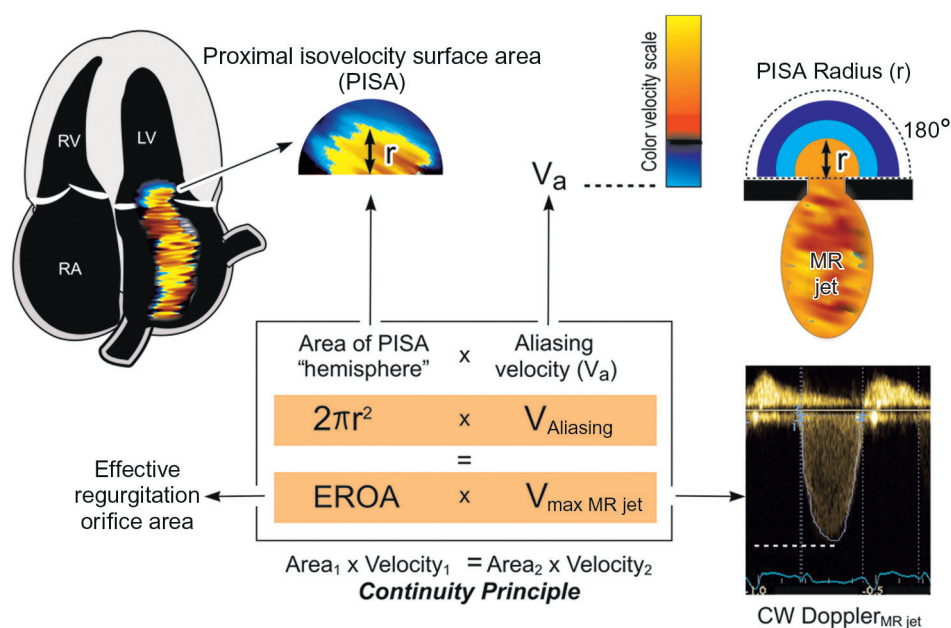

FIGURE 14-43 PISA approach to quantitating the EROA for MR. To optimize the PISA shell the baseline is shifted in the direction of the jet. EROA is computed as $\text{EROA} = 2(\pi r^2)(V_{\text{aliasing}})/(V_{\text{maxMR}})$. Regurgitant volume can be calculated as $\text{EROA} \times \text{VTI}_{\text{MR}}$, where VTI_{MR} is the velocity-time integral of the MR spectrum.

of three-dimensional capability, a systematic approach to assessment of all three scallops via two-dimensional TEE can be used (see Fig. 14-36). Complete assessment of the mitral scallops is difficult with TTE, although when achievable, high-quality three-dimensional TTE images may be used for this purpose.

Functional Mitral Regurgitation

The term *functional MR* refers to MR that has as its root cause LV systolic dysfunction and remodeling. When the dysfunction is on the basis of CAD, the term *ischemic MR* is used. On three-dimensional echocardiography it has been shown that functional/ischemic MR reflects an imbalance between the forces that close versus those that tether the mitral leaflets. The end result is pathologic tethering seen as apical displacement of leaflet coaptation. This pattern, which is appreciable on parasternal long-axis or apical views, is the echocardiographic hallmark of functional/ischemic MR (see Fig. 14-41). Reduced closing forces are attributable to impaired LV systolic

function, whereas pathologic tethering forces can occur because of traction on the mitral leaflets from either their annular insertion (as a result of annular dilation and/or reduced annular contraction) or from their chordal connection to the papillary muscles. The latter has been shown to result from geometric displacement of the papillary muscles because of global or regional remodeling. It has been shown convincingly that papillary muscle contractile dysfunction per se does not cause functional/ischemic MR.

Quantitation of Mitral Regurgitation

The ASE recommends an integrated approach to the quantitation of MR⁶⁹ that incorporates semiquantitative measures such as assessment of jet area, the size of the peak mitral E wave, vena contracta diameter, and pulmonary venous flow patterns. The peak E velocity reflects the initial diastolic gradient between the left atrium and left ventricle and will be elevated when MR has resulted in elevation of LA pressure. The vena contracta is the narrowest region of a jet and is best assessed in zoom mode on the parasternal long-axis view. Pulmonary venous flow patterns reflect the impact of the MR jet on flow into the left atrium with, in some cases, severe regurgitant systolic flow reversal. Quantitation of regurgitant volume and the EROA is possible with the PISA approach, which is based on the concept of acceleration of flow proximal to the regurgitant orifice (Fig. 14-43; see also Fig. 63-32). The quantitative Doppler approach that uses the continuity equation provides a means of calculating regurgitant volume and regurgitant fraction by comparing the total antegrade flow across the mitral valve with that across a nonstenotic nonregurgitant reference valve, typically the aortic valve (Fig. 14-44).

Even though the color jet size approach is easy, it is influenced by machine settings. It also underestimates MR severity with eccentric jets and overestimates severity with nonholosystolic MR. The PISA method is limited in situations in which the assumption of a hemispheric PISA shell and circular regurgitant orifice is invalid, as may be encountered with eccentric jets caused by degenerative MR, as well as in many cases of functional/ischemic MR. In nonholosystolic MR, the EROA calculated with the PISA approach will overestimate severity because it reflects the maximum rather than the EROA averaged over all of systole. The major limitation of the quantitative Doppler technique lies in the assumption of circular or oval mitral orifice geometry in calculating transmitral flow. The use of LV SV calculated from echocardiographically measured LV volume versus aortic outflow has been suggested as an alternative approach. The advent of three-dimensional echocardiography has provided methods for direct planimetry of regurgitant orifices and has optimized assessment of nonhemispheric PISA shells, but these methods are not yet widely used clinically.

It is important to recognize that functional MR and, to a lesser degree, MR of other causes is afterload dependent and hence determination of severity must take into account LV systolic pressure. Clinical decision making based on severity determinations made under general anesthesia is to be avoided because anesthesia is associated with a predictable fall in systemic vascular resistance, which may dramatically reduce the degree of regurgitation.

FIGURE 14-44 Quantitative Doppler approach to assessing the severity of MR. Regurgitant volume (RV) is calculated as the difference between total transmitral flow (Q_v) and antegrade flow across the LVOT (Q_s). Q_v and Q_s are calculated via the continuity method approach ($CSA \times VTI$). Alternatively, Q_v , which is identical to LV SV in the absence of a ventricular shunt or aortic regurgitation, may be calculated as $LVEDV - LVESV$, where LVEDV and LVESV are the LV end-diastolic and end-systolic volumes, respectively. A3C = apical three chamber; ALAX = apical long axis; RA = right atrium.

Aortic Valve

Aortic Valve Anatomy

The normal aortic valve consists of three symmetric cusps that are supported by the aortic annulus and extend into the aortic root. The right and left coronary cusps lie within the sinuses of Valsalva that give rise to the corresponding coronary arteries, and the remaining cusp is termed the noncoronary cusp. The ideal views for assessing aortic valvular anatomy are the parasternal short- and long-axis views (see Fig. 14-10) and their comparable views on TEE (see Fig. 14-23E, F). The short-axis view shows all three cusps, which when open create a triangular-shaped orifice and when closed have a Y-shaped appearance. The long axis typically displays the right and noncoronary cusps, which when normally open, will flatten against the walls of the aortic root and with normal closure will meet centrally without prolapse below the plane of the aortic annulus.

The most common congenital abnormalities of the aortic valve result from failure of cusp development and include, in order of decreasing frequency, bicuspid, unicuspid, and quadricuspid valves (Fig. 14-45). Bicuspid valves can be distinguished on the basis of the position of the coronary arteries relative to the line of closure. When both coronaries arise on the same side, the commissure is termed horizontal, whereas with a vertical commissure, the coronaries arise on opposite sides. Because of the inability of bicuspid valves

FIGURE 14-45 Congenital abnormalities of the aortic valve with (top to bottom) systolic short-axis, diastolic short-axis, and systolic long-axis views. **Left panels,** Bicuspid aortic valve. **Middle panels,** Unicuspid unicommissural aortic valve. **Right panels,** Quadricuspid aortic valve. Ao = aorta; LV = left ventricle.

to open fully, the systolic orifice of a bicuspid aortic valve is oval when seen in short axis, whereas the long axis view demonstrates protrusion of one or both cusp tips into the aortic lumen (doming). Although bicuspid aortic valves classically have a single line of closure, many such valves additionally have an echogenic ridge or raphe that represents a vestigial commissure. The closed appearance of such valves may be echocardiographically indistinguishable from a tricuspid valve. Thus a bicuspid aortic valve is a systolic diagnosis. Unicuspid valves typically have circular openings that may be central or asymmetrically positioned, and quadricuspid valves have a square appearance in systole and a crosslike appearance in diastole.

Congenital abnormalities of the LVOT include subaortic membranes, characterized by linear echoes extending from the anterior mitral leaflet to the septum or fibromuscular tunnels in which there is an echogenic ridge extending into the LVOT (Fig. 14-46). The presence of subaortic systolic turbulence should prompt close inspection of the LVOT for evidence of obstruction. Associated aortic valvular regurgitation is seen frequently and results from valve trauma caused by the subaortic stenotic jet. Supravalvular aortic stenosis is a rare phenomenon that consists of localized or diffuse narrowing of the ascending aorta distal to the sinuses of Valsalva.

FIGURE 14-46 Nonstandard parasternal long-axis view demonstrating a sub-aortic membrane (arrow). The image is angled to show the membrane well with the result that the aortic valve (AV) is not well seen. LA = left atrium.

Valvular Aortic Stenosis

Although the impeded cusp excursion of a bicuspid or unicuspid aortic valve may alone result in aortic stenosis, calcium deposition on a congenitally normal tricuspid aortic valve is a common cause of aortic stenosis in adults. The echocardiographic appearance is restricted cusp excursion with irregular nodular cusp thickening (Fig. 14-47).

Quantitation of Severity

The normal aortic valve area is 3 to 4 cm². Application of the Bernoulli equation to CW Doppler interrogation of transvalvular flow provides accurate measures of the mean and peak instantaneous gradients in aortic stenosis. Typically, the simplified form of the equation ($\Delta P = 4 V^2$) may be used, but when LVOT velocity exceeds 1 meter/sec, the expanded version, $\Delta P = 4 (V_2^2 - V_1^2)$, where V_2 is transaortic velocity and V_1 is LVOT velocity, should be used.

In recognition of the importance of recording Doppler signals parallel to flow, aortic gradients are best recorded from the apical five- or three-chamber, suprasternal notch, and right parasternal windows; commonly, the highest velocities are found on the right parasternal view. The smaller footprint provided by the nonimaging Pedoff probe makes it essential for optimal assessment of patients with aortic stenosis. When TEE is used, velocities are recorded from the deep transgastric views (see Fig. 14-23, position O). It should be noted that although echocardiographically derived mean gradients are generally identical to those obtained invasively, the echocardiographically derived peak instantaneous gradient is typically higher than the peak-to-peak gradient calculated in the catheterization laboratory. The latter is the arithmetic difference between peak LV and aortic pressure (Fig. 14-48; see also Fig. 19-13), which may not be coincident in time.

Although gradients alone provide a reasonable assessment of the severity of aortic stenosis when transaortic flow is normal, they may underestimate severity in the setting of low-flow states and overestimate severity when flow is elevated (e.g., high-output states such as those caused by sepsis and anemia). For this reason it is important to determine aortic valve area. Direct planimetry of TEE images may be used for this purpose, but TTE planimetry is not sufficiently accurate. The most common approach therefore is by application of the continuity equation (Fig. 14-49). Aortic valve area is calculated as

$$AVA = (CSA_{LVOT} \times VTI_{LVOT}) / VTI_{AV}$$

Less desirable is the simplified version

$$AVA = (CSA_{LVOT} \times V_{LVOT}) / V_{AV}$$

where V represents peak velocity. The CSA of the LVOT is typically calculated by assuming circular geometry with the formula

FIGURE 14-47 Systolic transesophageal images of valvular aortic stenosis in a patient with a tricuspid valve. **Left**, Two-dimensional long axis. There is minimal opening of the valve. **Middle**, Short axis. **Right**, Three-dimensional image. The latter two views better demonstrate the distribution of calcium.

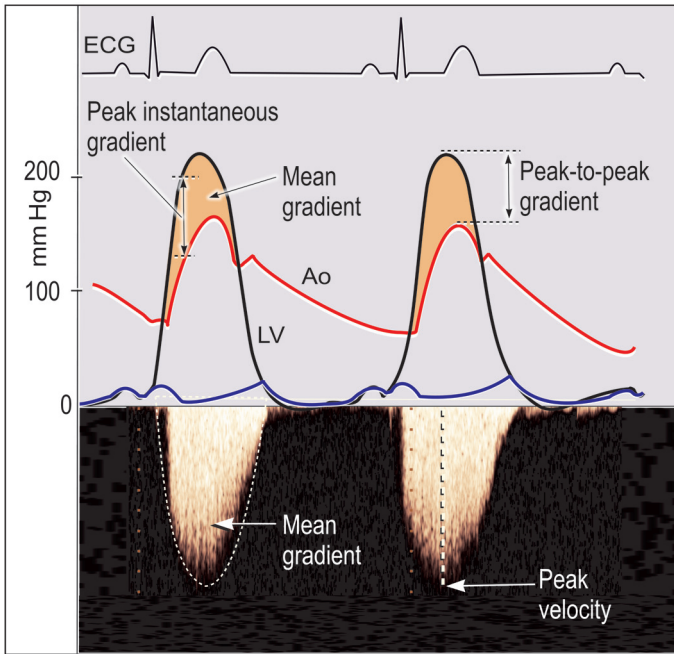

FIGURE 14-48 Doppler methods provide peak instantaneous and mean gradients. The peak instantaneous gradient is typically higher than the peak-to-peak gradient calculated from invasively measured peak LV and aortic (Ao) pressure, which is not instantaneous, although mean gradients measured with both techniques are identical.

FIGURE 14-49 Continuity equation approach to calculating aortic valve area. The CSA of the aortic valve (CSA_{AV}) is calculated as $(CSA_{LVOT} \times VTI_{LVOT}) / VTI_{AV}$. LVOT cross-sectional area is calculated as $\pi(D/2)^2$, where D is LVOT diameter. LVOT VTI should be measured from the modal rather than the maximal velocity.

$CSA = \pi(D/2)^2$, where D is the systolic LVOT diameter measured on the parasternal or TEE-equivalent long-axis view. According to the ASE convention the diameter is measured just proximal to the aortic annulus. It should be noted that because the LVOT velocity incorporated into the calculation is the modal velocity, displayed as the densest part of the pulsed Doppler envelope, the VTI should not be traced by using the outer edge of the spectrum, which represents the maximal (not modal) velocity at each time point (Fig. 14-50). Optimal sample volume placement is in the LVOT immediately proximal to the site of subvalvular flow acceleration, typically 1 to 2 mm proximal to the valve on the apical five- or three-chamber (TTE) or deep transgastric (TEE) views.

FIGURE 14-50 Doppler spectra demonstrating the error that may be introduced if the maximal (white dotted line) rather than the modal (red dotted line) velocity is measured. The modal velocity (the most commonly occurring velocity) corresponds to the darkest portion of the Doppler spectrum.

Low-Gradient Severe Aortic Stenosis

In the setting of reduced SV because of LV systolic dysfunction, the calculated effective orifice area may be small despite low gradients, and it becomes important to determine whether the valve obstruction is fixed (severe aortic stenosis) or the valve is intrinsically capable of opening more fully at higher flow rates (pseudosevere aortic stenosis). As noted previously (see the section [Stress Echocardiography in Valvular Heart Disease](#)), DSE is routinely used in this setting, typically with close physician supervision to evaluate the true aortic valve area, as well as LV contractile reserve. The effective orifice area may also be severely reduced despite low gradients when the LVEF is within the normal range but SV is impaired, so-called paradoxical low-gradient preserved ejection fraction severe aortic stenosis.

Subvalvular or Supravalvular Aortic Stenosis

CW Doppler echocardiographic assessment of peak and mean gradients is the cornerstone in evaluating patients with LVOT obstruction below or above the valve. However, by readily demonstrating the site of flow acceleration, color Doppler may provide a clue that the obstruction is not at the level of the valve and prompt the more detailed imaging evaluation that is necessary to clarify the pathophysiology. In some patients, evaluation is complicated by the presence of obstruction at multiple levels. In such cases, because of the trade-off between range resolution and the inability to accurately measure the high velocities inherent in the PW Nyquist limit, it may be impossible to accurately delineate the gradients created at each level of obstruction.

Aortic Regurgitation

Aortic regurgitation may result from abnormalities in the valve cusps, normal cusps whose coaptation is altered by enlargement of the annulus and/or sinuses or, rarely, prolapse of an aortic dissection flap through the valve (see the section [Aortic Diseases](#)). Echocardiographic imaging (TTE and TEE) will establish a causative diagnosis (see Fig. 63-13) and typically demonstrates LV end-diastolic enlargement if the regurgitation is hemodynamically significant. High-frequency fluttering of the anterior mitral leaflet caused by the impact of the regurgitant jet may be evident on M-mode, and in cases of acute severe regurgitation the mitral valve may close prematurely before ventricular systole because of a rise in LV pressure exceeding the LA pressure before ventricular contraction.

FIGURE 14-51 Methods of quantitating aortic regurgitation (AR). A pressure half-time (PHT) greater than 500 milliseconds suggests mild AR, 200 to 500 milliseconds suggests moderate AR, and less than 200 milliseconds suggests severe AR. Holodiastolic flow reversal in the descending thoracic aorta, as shown here, is consistent with at least moderate AR. S = systole; D = diastole.

The diagnosis of aortic regurgitation is most easily made when a diastolic color Doppler jet is seen in the LVOT. Small transient jets can be normal variants. The ASE recommends an integrated approach to determination of the severity of aortic regurgitation,⁶⁹ with elements including evidence of LV enlargement, color jet dimensions, spectral Doppler signal intensity, pressure half-time, vena contracta, and diastolic flow reversal in the descending thoracic or abdominal aorta. Regurgitant volume and regurgitant fraction can be calculated via a continuity-based approach, and both regurgitant volume and EROA may be calculated with the PISA approach.

Color jet dimensions should be assessed with Nyquist settings of 50 to 60 cm/sec. The best dimensional predictors of angiographic severity are jet area indexed to the LV short-axis area (parasternal short-axis view) and jet diameter indexed to LVOT diameter immediately proximal to the valve (parasternal long-axis view). Jet length is not a reliable index of severity. The pressure half-time reflects the rate at which aortic and LV pressures equalize and is most reliable in the setting of acute regurgitation, as long as care is taken to ensure that the early diastolic velocity is captured accurately (Fig. 14-51). The vena contracta is the waist (smallest diameter) of the aortic regurgitant flow jet at the level of the valve measured in zoom mode on a parasternal long-axis or TEE-equivalent view. Holodiastolic flow reversal in the descending thoracic aorta as detected with the pulsed Doppler sample volume placed near the origin of the left subclavian artery is a marker of at least moderate regurgitation (see Fig. 14-51). Reversal of comparable duration as measured in the abdominal aorta generally reflects severe regurgitation. Although the PISA approach that is widely used to assess the severity of MR and TR has similarly been used to calculate EROA and regurgitant volume for aortic regurgitation, it may be challenging to accurately measure the PISA radius when only mild regurgitation is present (particularly with TTE). The quantitative Doppler approach that calculates regurgitant volume by comparing flow through the LVOT with that across a competent non-stenotic valve is most robust when the pulmonic valve is used as the reference for normal flow (image quality permitting). The mitral valve can theoretically be used as the reference but is more geometrically complex and hence more prone to error.

Tricuspid Valve

Tricuspid Valve Anatomy. The tricuspid valve is anatomically complex, with anterior, posterior, and septal leaflets extending from the tricuspid annulus to chords and variable papillary muscle/trabecular attachments. Even though the anterior and septal leaflets are well seen on multiple echocardiographic views, the posterior leaflet is

FIGURE 14-52 Right ventricular inflow tract view demonstrating diastolic doming of the posterior leaflet (arrow) characteristic of rheumatic tricuspid valve disease. RA = right atrium; RV = right ventricle.

visualized only on the RV inflow tract view and on short-axis views of the right ventricle (which can display all three leaflets). Because of its importance in imaging the tricuspid valve, the RV inflow tract view must be acquired in a manner that displays the inferior (diaphragmatic) wall but avoids the interventricular septum and septal leaflet of the tricuspid valve (see Fig. 14-10).

Acquired Disorders of the Tricuspid Valve. Tricuspid stenosis occurs in approximately 11% of patients with rheumatic mitral disease and is characterized by diastolic leaflet doming, as well as by leaflet and chordal thickening (Fig. 14-52). Severity is best assessed by Doppler-derived mean gradients. Methods for calculating valve area, including the pressure half-time approach, have not been validated for tricuspid stenosis.

Pathologic TR most commonly occurs on a functional basis, that is, attributable to RV enlargement and/or dysfunction. RV abnormalities may be primary or secondary to pulmonary hypertension and/or left-sided cardiac abnormalities. The echocardiographic hallmark of functional TR is apical tethering, which when severe may result in a visible regurgitant orifice (noncoaptation of the leaflets) (Fig. 14-53). Under these conditions the regurgitant jet could be laminar and relatively low velocity because of the almost complete equalization of pressures between the right ventricle and the right atrium and lead to underestimation of the severity of the TR. Similarly, estimation of pulmonary artery systolic pressure from TR jet velocity will be inaccurate in this situation.

Less common acquired causes of TR include carcinoid, rheumatic disease, endocarditis, trauma (including iatrogenic injury to the valve during RV biopsy), pacemaker and defibrillator wires, and myxomatous disease with prolapse. The characteristic echocardiographic appearance of carcinoid heart disease is drumstick-like rigid and shortened leaflets with, at times, a visible regurgitant orifice (Fig. 14-54; see also Fig. 63-42). Spontaneous flail of the tricuspid valve virtually never occurs. Myxomatous tricuspid valve disease has been less well studied than mitral disease, with less clear-cut criteria for the diagnosis of prolapse. It frequently accompanies myxomatous mitral disease.

Quantitation of Tricuspid Regurgitation. Quantitation of TR is similar to that for MR and consists of the integrated approach recommended by the ASE,⁶⁹ including measures of jet size, vena contracta, and PISA-derived regurgitant volume and EROA. Systolic flow reversal into the hepatic veins is specific for severe TR.

Pulmonic Valve

Pulmonic Valve Anatomy. The normal pulmonic valve is tricuspid with a structure that is similar to that of the aortic valve. The cusps are named right, left, and anterior, although it is unusual to be able to see all three cusps simultaneously with two-dimensional imaging. The pulmonic valve can be seen on parasternal and subcostal views, as well as on anteriorly oriented apical views. TEE windows include

FIGURE 14-53 Right ventricular inflow tract view showing failure of coaptation of the anterior and posterior leaflets (arrow) in a patient with severe functional TR. Severity may be underestimated because of its low velocity and monochromatic appearance (right panel). RA = right atrium; RV = right ventricle.

FIGURE 14-54 Apical four-chamber view showing the drumstick appearance of the tricuspid valve (arrow), which is characteristic of carcinoid valvopathy. RA = right atrium; RV = right ventricle.

FIGURE 14-55 PW Doppler interrogation of the RVOT in a patient who has undergone pulmonary valvotomy. There is severe pulmonic regurgitation resulting in a laminar regurgitant signal.

the midesophageal, deep transgastric, and high esophageal (at the level of the aortic arch). The most common congenital anomaly is valvular stenosis on the basis of developmental abnormalities that mimic those of a bicuspid aortic valve (Fig. e14-11). It is characterized by systolic doming and a jump rope–like appearance of the valve. Congenital pulmonic stenosis may be isolated or occur as a feature of more complex congenital anomalies. Acquired pulmonic disease is rare and includes carcinoid and endocarditis, as well as iatrogenic disruption of the valve because of balloon or surgical valvuloplasty for congenital stenosis.

Quantitation of Valve Dysfunction. Pulmonic stenosis is most reliably quantitated with mean and peak gradients, although the continuity equation provides a means of calculating valve area. Pulmonic regurgitation is most commonly quantitated on the basis of jet dimensions, with the caveat that there may be little turbulence in the setting of severe regurgitation with normal pulmonary pressure and the possibility that its severity may be underestimated. Laminar regurgitant flow is a clue to severe regurgitation (Fig. 14-55).

Prosthetic Valves

Echocardiographic assessment of prosthetic valves requires an understanding of valve design, normal functional characteristics, and the imaging artifacts introduced by valve elements (see Chapter 63).

The most commonly encountered mechanical valves are bileaflet or single tilting disc valves, although ball-and-cage valves, which are no longer implanted, are occasionally encountered (see Fig. 63-45). Most bioprosthetic valves are stented porcine or bovine pericardial valves, although freestyle (stentless) xenograft, cadaveric homograft, autograft (Ross procedure), and transcatheter and sutureless surgical valves are also available. Prosthetic annular rings are also commonly used for mitral and tricuspid repair. The sewing rings of all valves, as well as the occluders of mechanical valves, may cause acoustic shadowing that limits imaging and Doppler assessment. Additionally, the material of the ball in ball-and-cage valves transmits sound more slowly than human tissue does, with the result that the ball appears much larger than its actual size when imaged echocardiographically.

Even normally functioning prostheses tend to be intrinsically stenotic, with the degree of stenosis inversely related to valve size. Additionally, trivial degrees of valvular regurgitation are normal findings, and although not normal, trivial paravalvular regurgitation is not uncommon. Intraventricular microcavitations (apparent “microbubbles”) are often seen in the presence of mechanical valves and are not considered abnormal. Figures 14-56 and 14-57 demonstrate the normal echocardiographic appearance of the most commonly seen prostheses. Note that the echocardiographic appearance of

FIGURE e14-11 Systolic parasternal short-axis view demonstrating systolic doming of this congenitally stenotic pulmonic valve (*arrow*). In real time the valve has a jump rope appearance.

stentless, homograft, and autograft valves (not shown) may be indistinguishable from that of native valves. **Table 14-11** provides normal echocardiographic values for the most commonly implanted valves.⁷⁰ A rule of thumb, helpful when valve size is unknown, is that for commonly sized prostheses with physiologic heart rates and SV, the peak

transaortic velocity should be less than 3 meters/sec and the mean transmitral gradient should be 5 mm Hg or lower.

The echocardiographic approach to prosthetic valves is similar to but often more challenging than that of native valves. Peak and mean gradients are calculated by using the conventional application of the

Bernoulli equation, and effective orifice area may be calculated with the continuity equation. Additionally, the Doppler velocity index, defined as the ratio of the VTI (or alternatively, peak velocity) proximal to the valve to that distal to the valve, provides an alternative metric of aortic prosthetic function that is useful when LVOT diameter cannot be measured. Just as for native valves, it is critical that LVOT sampling be proximal to the site of flow acceleration; in the case of transcatheter or sutureless valves the sampling volume should be proximal to the inlet of the metal frame because in these valves there is acceleration of flow at the inlet, as well as at the level of the cusps. For mitral prostheses, the comparable measure is the ratio of mitral to aortic VTI. In the setting of atrial fibrillation, matching of cycle lengths for beats used for LVOT and valvular VTIs is preferred to averaging over multiple beats. Beats corresponding to physiologic heart rates should be used if available. Although the pressure half-time may be useful in a relative sense in patients with mitral prostheses, it is important to recognize that it does not provide a valid measure of effective orifice area.

In many centers, intraoperative TEE is performed routinely during valve procedures, and these studies can both alert the surgeon to remediable complications before chest closure and serve as reference studies for follow-up evaluation. It is also recommended that TTE be performed soon after implantation to define the baseline appearance and structure with this modality and under more physiologic conditions than those present in the immediate postpump period. For all studies, chamber dimensions and function and estimated pulmonary artery systolic pressure, as well as heart rate, blood pressure, and body surface area, should be included in the report. Before postoperative echocardiographic evaluation it is important to obtain information on valve type and size and details of the valve implantation when possible.

Abnormalities in Valve Appearance

Abnormalities in valve appearance include evidence of an unusual implantation position or valvular dehiscence, which when extensive is characterized by pathologic valve rocking. Although extensive bioprosthetic cusp thickening is typically associated with functional disturbance (see later), mild abnormalities may not affect valve function. Similarly, valve vegetation and thrombus may be functionally silent. Therefore echocardiographic evaluation must pay close attention to structure even when function is normal, with TEE being performed if TTE images are nondiagnostic.

Echocardiographic Approach to Assessing Elevated Prosthetic Gradients

The diagnosis of prosthetic stenosis is suggested when gradients are elevated and the effective orifice area is reduced relative to published norms. For aortic prostheses, a Doppler velocity index that is less than 0.25 and/or a ratio of acceleration to ejection times greater than 0.4 supports the diagnosis, as does a pressure half-time longer than 200 milliseconds, peak E wave greater than 1.9 meters/sec, or VTI_{MV}/VTI_{LVOT} of 2.2 or higher for mitral prostheses. As with native valves, gradients must be interpreted in the context of heart

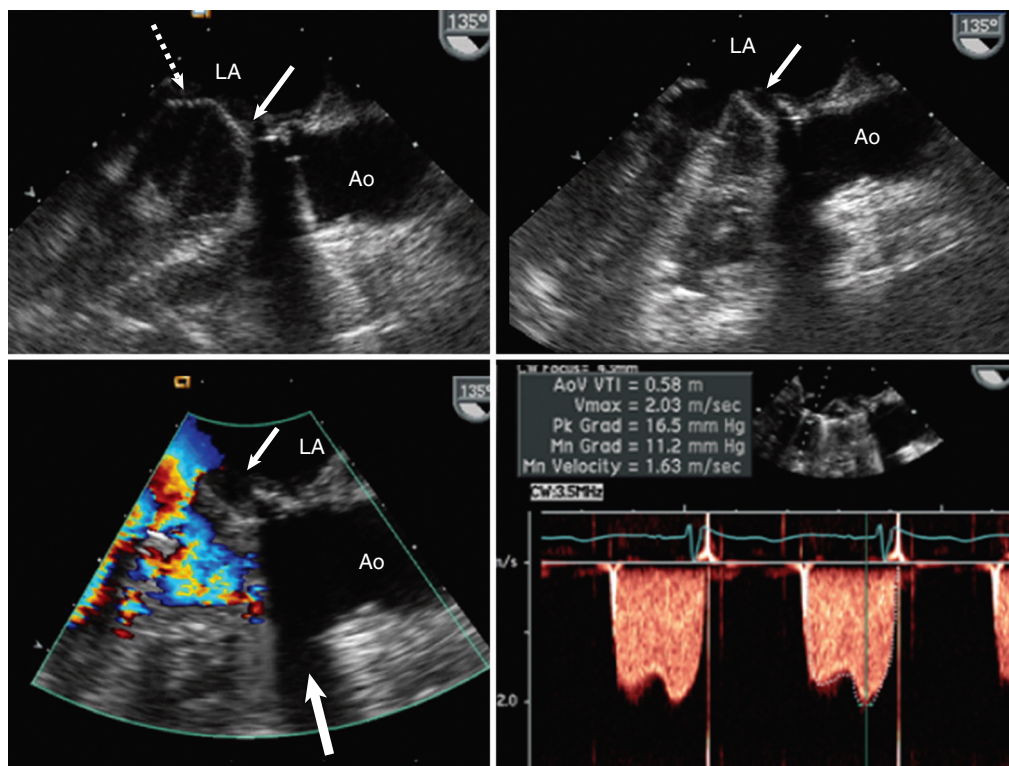

FIGURE 14-58 TEE showing a bileaflet mechanical mitral prosthesis in which one disc is immobilized because of thrombus. **Upper left**, Systolic frame showing that neither disc (arrows) closes completely. **Upper right**, While the left disc opens fully, the right disc is immobile. **Lower left**, Color flow Doppler demonstrating high-velocity flow through a single orifice. The large arrow indicates acoustic shadowing because of the mitral sewing ring. **Lower right**, Doppler demonstrating an elevated transmitral gradient (11.2 mm Hg at a heart rate of 65 beats/min). Ao = aorta; LA = left atrium.

rate. Causes of prosthetic stenosis include restricted leaflet/disc motion because of thrombus (Fig. 14-58), pannus ingrowth (Fig. 14-59), vegetation, or in the case of bioprostheses, cusp degeneration often with calcification (Fig. 14-60). Differentiation between pannus and thrombus may be challenging, although thrombi tend to have a softer echotexture than pannus does and may be larger with extension beyond the sewing ring. Clinical factors suggesting thrombus include the acuity of symptom onset and a history of inadequate anticoagulation. Because the restricted motion may be intermittent, it is important to capture multiple beats if prosthetic dysfunction is clinically suspected. TEE is frequently required to optimally image valves, and fluoroscopy may be helpful when abnormal occluder motion is suspected in mechanical valves.

It is important to note that elevated gradients do not always reflect prosthetic stenosis. Patient-prosthesis mismatch (PPM) refers to the situation in which the implanted valve, although functioning normally, has elevated gradients (see Chapter 63). This occurs when patient anatomy results in the implantation of a smaller than ideal valve. The diagnosis is made by confirming that the calculated effective orifice area is consistent with normal function but the indexed orifice area is $0.85 \text{ cm}^2/\text{m}^2$ or less for aortic prostheses and less than $1.2 \text{ cm}^2/\text{m}^2$ for mitral prostheses. For aortic prostheses, an indexed effective orifice area of less than $0.65 \text{ cm}^2/\text{m}^2$ is considered severe PPM, a phenomenon encountered in 2% to 11% of patients. PPM is a phenomenon best studied for the aortic valve and has been reported to be associated with poorer outcomes,⁷¹ although in obese patients it is unclear whether the indexed effective orifice area should be calculated on the basis of lean rather than actual body mass.

Elevated gradients may also be a consequence of significant regurgitation, which when paravalvular, may be underappreciated on initial evaluation. A final important cause of elevated gradients, pressure recovery, refers to the tendency for Doppler-derived aortic prosthetic gradients to overestimate those registered invasively. This occurs because Doppler measures the largest gradient, typically encountered at the vena contracta, whereas invasive measurements reflect pressure distal to the valve where there has been recovery either because blood has moved from the narrow valve orifice into the wider aorta (i.e., a

FIGURE 14-59 TEE appearance of pannus ingrowth (arrow) in a mitral bioprosthesis. **Left**, Systole. **Right**, Diastole. Note that the pannus has immobilized the base of the left-sided cusp and created a hinge point midway along the cusp and an narrow orifice. LA = left atrium. LV = left ventricle.

FIGURE 14-60 TEE demonstrating a degenerated bioprosthesis. **Left**, Diastolic frame showing grossly restricted cusp motion. **Middle**, Color Doppler demonstrating turbulent transmitral flow and an easily identifiable proximal isovelocity hemispheric surface area shell. **Right**, Three-dimensional TEE view of the prosthesis from a left atrial perspective. The mitral orifice is greatly restricted.

flask-shaped aortic root and a significant factor only in the setting of aortas measuring <3 cm) or, in the case of bileaflet mechanical valves, because the lower pressure encountered in the central orifice is augmented by higher pressure cause by eddies at the lateral orifices. Pressure recovery is most important clinically in the setting of small (≤ 19 mm) bileaflet valves in the aortic position. It has been shown that measurements most representative of invasive gradients will be obtained by carefully interrogating the lateral orifices, but this generally requires TEE. Alternatively, it has been suggested that gradients recorded through the central orifice may be corrected by applying the pressure loss coefficient of 0.64. It should be noted, however, that the reported normal values provided in [Table 14-11](#) are uncorrected.

Prosthetic Regurgitation

Trivial degrees of valvular regurgitation are normal findings, although the location of normal jets varies depending on the valve type. Pathologic regurgitation may be valvular and arise within the sewing ring or be paravalvular, exterior to the sewing ring. Valvular regurgitation in mechanical valves typically reflects occluder malfunction as a result of pannus, thrombus, vegetation, or rarely, retained mitral valve apparatus, whereas in bioprostheses, this is typically a result of cusp degeneration or disruption because of endocarditis (see [Fig. 64-3](#)). Paravalvular regurgitation may be a residual finding resulting from suboptimal implantation or develop de novo as a result of endocarditis or spontaneous valve dehiscence. Some degree of paravalvular regurgitation is a common finding following transcatheter aortic valve implantation (see [Chapter 56](#)) ([Fig. 14-61](#)).

Detection of prosthetic regurgitation may require nonstandard views. Quantitation of prosthetic regurgitation may be challenging

FIGURE 14-61 Deep transgastric transesophageal view of a balloon-expandable aortic prosthesis with paravalvular (dotted arrow) and valvular (solid arrow) regurgitation. Ao = aorta; LV = left ventricle; RV = right ventricle.

because jets are frequently highly eccentric and may be multiple, thus limiting the value of approaches based on jet dimensions. Assessment of paravalvular regurgitation in transcatheter or sutureless valves is particularly difficult inasmuch as multiple pinhole jets may be present.⁷² For aortic regurgitation, the presence of a shortened

pressure half-time (<200 milliseconds) and holodiastolic flow reversal in the descending thoracic or abdominal aorta are clues to significant regurgitation. For mitral prostheses, findings of pulmonary venous flow reversal, an elevated E wave, and VTI_{MV}/VTI_{LVOT} of 2.2 or higher should raise suspicion for significant regurgitation. The quantitative Doppler approach using the pulmonic valve as the reference may also be helpful for aortic prostheses. Regurgitant volume values lower than 30, 30 to 59, and 60 mL or higher and regurgitant fraction values lower than 30%, 30% to 50%, and higher than 50% are consistent with mild, moderate, and severe regurgitation, respectively. For mitral valves, the presence of well-defined flow convergence suggests significant regurgitation, and the PISA approach may be used to quantitate central valvular or well-defined single paravalvular jets. Finally, new three-dimensional TEE approaches to direct planimetry of the regurgitant orifices show promise in more accurately localizing and characterizing the extent of paravalvular dehiscence.

Prosthetic tricuspid and pulmonic valves are much less common than their left-sided counterparts. In general, methods developed for assessment of the mitral and aortic valves are extrapolated to the tricuspid and pulmonic valves, although the evidence base for their use is less robust.

PERICARDIAL DISEASE (see Chapter 71)

Echocardiography is the imaging modality of choice for the identification of pericardial effusion and is an important tool in the diagnosis of tamponade and pericardial constriction.

Pericardial Effusion

Identification of pericardial effusion was one of the earliest applications of echocardiography. The diagnosis is made when an echo-free space separates the visceral and parietal pericardial echoes throughout the cardiac cycle, including diastole (Fig. 14-62). Systolic separation alone may be a normal finding. In most cases the diagnosis of pericardial effusion is straightforward because the parietal pericardium is a strong echo reflector and the visceral pericardium is

FIGURE 14-62 Pericardial effusion. A parasternal long-axis view shows both pericardial effusion (PE) and pleural effusion (short arrow). Note that the descending thoracic aorta (long arrow) is displaced from the heart by the pericardial effusion. With isolated pleural effusion, the descending aorta (Ao) remains immediately posterior to the heart. In this case the pericardial effusion extends posterior to the left atrium (LA), although such is not always the case. RV = right ventricle; LV = left ventricle.

adherent to the epicardial surface of the heart. “Echo free” is defined as having an echotexture that is equivalent to that of the intracardiac blood pool. Although it is typically black, there may be cases in which suboptimal image quality results in both blood pool and pericardial effusion having a somewhat gray or intermediate echotexture. In such cases it may be difficult to differentiate a small pericardial effusion from epicardial fat, although the latter typically has a more reticulated inhomogeneous appearance than effusion does.

Another source of confusion may be left pleural effusion. Differentiating features include displacement of the aorta from the heart by pericardial (but not pleural) fluid and extension of pleural (but not pericardial) fluid behind the left atrium (see Fig. 14-62). Of the two features, the relative position of the aorta is the most definitive because the position of the pericardial reflection is somewhat variable. Pericardial effusions may extend cephalad beyond the atrioventricular groove. It is therefore essential that sonographers routinely provide views that demonstrate the descending thoracic aorta and its position relative to the heart.

Sizing of pericardial effusions is typically somewhat subjective, with the terms trace, small, medium, and large being used. For reporting the size of effusions in which longitudinal comparison will be important, it is helpful to report the maximal diameter of the effusion while noting the view or views and time of the cardiac cycle (systole versus diastole) at which the measurement is taken. When effusions are uniformly distributed, an estimate of volume may be obtained by subtracting the volume of the heart from the volume of the pericardial sac (heart plus fluid) by using the formula ($\pi \times 4/3 \times L/2 \times D1/2 \times D2/2$), where L is the major axis and D1 and D2 are the orthogonal minor axes.

Pericardial Hematoma

Pericardial hematoma results from bleeding into the pericardial space and may occur as a result of bleeding along suture lines following open heart surgery, trauma, myocardial rupture, or aortic dissection or as a complication of catheter-based or surgical intervention. Hematomas typically have an echotexture that is more consistent with that of clot than free fluid and, accordingly, is more reticulated and echodense than that of free fluid. They may be unevenly distributed and localized to the bleeding site. When images are obtained in the acute setting, there may be evidence of both clot and free fluid (Fig. 14-63).

FIGURE 14-63 Pericardial hematoma. A subcostal view shows clotted (arrow) and free blood (black echotexture) within the pericardial space. In this patient the cause was acute aortic dissection. RA = right atrium, LA = left atrium, LV = left ventricle.

Echocardiographic Markers of Tamponade

Echocardiographic markers of cardiac tamponade (see Chapter 71) fall into two categories: (1) cardiac chamber invagination reflecting elevated intrapericardial pressure and the resultant pressure gradients across the chamber walls and (2) echocardiographic markers of pulsus paradoxus, which reflect exaggerated respiratory variation in left-sided heart filling and ejection relative to that of the right side of the heart.

RA inversion (Fig. 14-64, left panel) is a dynamic phenomenon whose onset occurs when RA volume and pressure are lowest: in late ventricular diastole immediately after atrial contraction. Inversion continues through a variable portion of ventricular systole and resolves as the right atrium fills and RA pressure rises. This sign can be detected in any view in which the RA wall and adjacent effusion are well seen, typically the parasternal short-axis view at the level of the great vessels and the apical four-chamber and subcostal four-chamber views. This sign is highly sensitive (100%) but may be present when there are hemodynamic disturbances that are invasively detectable but fall below the threshold for the clinical diagnosis of tamponade, with the result that the specificity for

clinical tamponade is 82%. Empirically, it has been shown that an RA inversion time index (readily calculated as the number of frames during which the right atrium is inverted divided by the number of frames per cardiac cycle) of at least 0.33 is associated with clinically evident tamponade (100% specificity, 95% sensitivity). LA inversion as a marker of tamponade is rare and typically occurs in the setting of loculated effusions or those in which the pericardial reflection is relatively high and the left atrium is exposed to the effects of intrapericardial pressure.

The onset of RV inversion (Fig. 14-64, right panel) occurs when RV volume and pressure are lowest—during isovolumic relaxation. It continues through a variable portion of ventricular diastole, with the RV contour normalizing as the ventricle fills and RV pressure rises. This sign is most easily detected on the parasternal long-axis view, which displays the RVOT. Its reported sensitivity is 82% to 94% with a specificity of 88% to 100%.

It is important to note that RA inversion and RV inversion are defined by actual wall invagination rather than by the normal flattening that may occur with respective chamber systole. They may also be absent (i.e., false negative) in the setting of underlying right-sided

heart dysfunction associated with elevated intracavitary pressure. With pericardial hematoma, in which no free blood is present, dynamic inversion of the chambers will not be observed, but the presence of fixed compression and underfilling of the cardiac chambers may be clues to the presence of tamponade physiology.

Echocardiographic correlates of pulsus paradoxus reflect exaggerated interdependence between the right and left ventricles within a tense fluid-filled pericardium. The most widely used signs are an exaggerated (>10%) inspiratory decrease in the mitral Doppler E wave and a corresponding increase in the tricuspid E wave (Fig. 14-65), as well as corresponding changes in systolic aortic and pulmonic wave Doppler spectra.

Pericardiocentesis

Echocardiography may also be useful in guiding needle pericardiocentesis, particularly in the setting of loculated

FIGURE 14-64 Signs of cardiac tamponade. **Left**, Apical four-chamber view showing RA inversion (arrow), a marker of tamponade. In this case, inversion, which is initiated in late ventricular diastole, has persisted well into ventricular systole. **Right**, Parasternal long-axis view showing RV collapse in diastole (arrow).

FIGURE 14-65 Doppler spectra showing the characteristic exaggerated respiratory variation in outflow (left panel) and inflow (right panel) Doppler spectra. On inspiration, right-sided flow increases with corresponding reductions in left-sided flow. EXP = expiration; INSP = inspiration.

FIGURE 14-66 Left, Parasternal long-axis view demonstrating thickened pericardium (between the arrowheads). Right, M-mode echocardiogram. The bright posterior echo (white arrow) representing the parietal pericardium moves in parallel with the visceral pericardial/epicardial echoes (blue arrow), a finding indicative of adhesion between the two layers. If the pericardial space were expanded by free fluid (pericardial effusion), the parietal pericardial echo would be relatively stationary.

effusions. Imaging may help identify the best puncture site and confirm that the needle has entered the pericardial space. The latter is accomplished by the injection of a small amount of agitated saline, which will opacify the pericardial effusion with proper needle placement but will result in intracardiac contrast bubbles should the needle have inadvertently penetrated the heart. Echocardiography can also document the reduction in effusion size that should occur with successful drainage.

Constrictive Pericarditis

Pericardial constriction occurs when there is thickening (Fig. 14-66), with or without calcification, of the pericardium that results in impaired cardiac diastolic filling, particularly during inspiration. The clinical features mimic those of biventricular heart failure, although the presence of a pericardial knock and Kussmaul sign (inspiratory increase in jugular venous pressure) should raise suspicion for constriction. Frequently, when the patient is referred for echocardiographic evaluation, the clinical differential diagnosis is restrictive cardiomyopathy versus pericardial constriction. Pericardial thickening is a hallmark of constriction but is a relatively insensitive finding. When the pericardial space is expanded because of adhesions and fibrous tissue, the visceral and parietal pericardia are separated by tissue of variable echogenicity, as opposed to the echo-free appearance of pericardial effusion. An additional differentiating feature is that with effusion, the parietal pericardial echo will be relatively stationary whereas with pericardial thickening, visceral and parietal pericardial echoes will move in tandem. Calcification will result in acoustic shadowing.

Restrictive and constrictive physiology share a mitral diastolic filling pattern characterized by a prominent E wave (E-to-A reversal) and shortened deceleration time, biatrial enlargement, a fixed dilated IVC that does not change size with a sniff, and typically normal ventricular systolic function. However, the two can be distinguished on the basis of the prominent respiratory changes that characterize constrictive physiology, as well as the fact that the mitral annular DTI waves generally have normal amplitude in constriction but are reduced with restriction. A DTI peak E' of 8 cm/sec or greater has been reported to have 89% sensitivity and 100% specificity for constriction. Restriction but not constriction is characterized by evidence of impaired relaxation, and thus the color M-mode propagation velocity is typically normal in constriction. In addition, pulmonary artery systolic pressure is unlikely to exceed 50 mm Hg in constriction.

In constriction the rigid pericardium abruptly limits filling when the fixed volume that it can accommodate is reached. When inspiration results in increased venous return to the right side of the heart, there is an obligatory reduction in the amount of blood that can be accommodated by the left ventricle. The echocardiographic correlates of this phenomenon are an exaggerated and abrupt inspiratory shift in the position of the interventricular septum toward the left ventricle

(Fig. 14-67) and exaggerated respiratory variation in the magnitude of the mitral and tricuspid E waves. Additional markers of constriction include premature opening of the pulmonic valve, which is most pronounced with inspiration (reflecting an end-diastolic rapid rise in RV pressure that exceeds pulmonary artery pressure), diastolic MR, and expiratory diastolic hepatic vein flow reversal (Fig. 14-68).

In digital echocardiography laboratories in which acquisitions are frequently limited to one- to two-beat clips, to assess the impact of respiration it is essential that longer captures with respiratory gating be obtained. M-mode echocardiography over multiple cycles is particularly useful for detection of septal bounce and pericardial thickening and may also demonstrate flattened diastolic motion of the posterior wall, as well as transient early diastolic posterior motion of the interventricular septum on inspiration.

It should be noted that fibrotic involvement extending from the pericardium into the myocardium may result in mixed constrictive-restrictive physiology. Echocardiographic reassessment after removal of the pericardial fluid that is causing tamponade may reveal unmasked constrictive physiology (effusive-constrictive physiology).

Malignant Involvement of the Pericardium

Malignant pericardial disease typically occurs on the basis of local spread or distal metastases, with lung and breast cancer being the most common primaries. Primary pericardial tumors are uncommon. The echocardiographic appearance may be that of pericardial effusion and/or tumor, which frequently extends into the myocardium (Fig. 14-69).

Other Pericardial Pathology

Congenital absence of the pericardium is a rare abnormality that commonly involves the left pericardium and is associated with a leftward shift in the position of the heart, as well as exaggerated translation, the net result being an echocardiographic pattern that mimics that of RV volume overload. A pericardial cyst is a benign abnormality that is typically detected as an incidental finding of an echo-free accumulation adjacent to the heart.

DISEASES OF THE AORTA (see Chapter 57)

TTE is a first-line tool to assess the thoracic aorta for pathologic processes.^{19,73} TTE can visualize the proximal aortic root and ascending aorta, aortic arch up to the isthmus (takeoff of the left subclavian artery), and limited portions of the descending thoracic and proximal abdominal aorta (Fig. 14-70). TEE can be used to more comprehensively examine the entire thoracic aorta (Fig. 14-71), with

Apical 4-Chamber Perspectives During Diastole

FIGURE 14-67 Schematic representing the echocardiographic manifestations of constriction that may be appreciated on the apical four-chamber view. Mitral (MV) and tricuspid (TV) valve Doppler spectra are characterized by an increased E/A ratio and shortened deceleration time. With inspiration there is increased venous return to the right side of the heart, which can be accommodated within the rigid pericardium only by displacement of the interventricular septum to the left and reduced left-sided filling. On expiration, left-sided filling increases, the septum moves to the right, and there is flow reversal in the hepatic veins. LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle. (Modified from Bulwer BE, Rivero JM [eds]: *Echocardiography Pocket Guide: The Transthoracic Examination*. Burlington, Mass, Jones & Bartlett Learning, 2011, 2013, p 141. Reprinted with permission.)

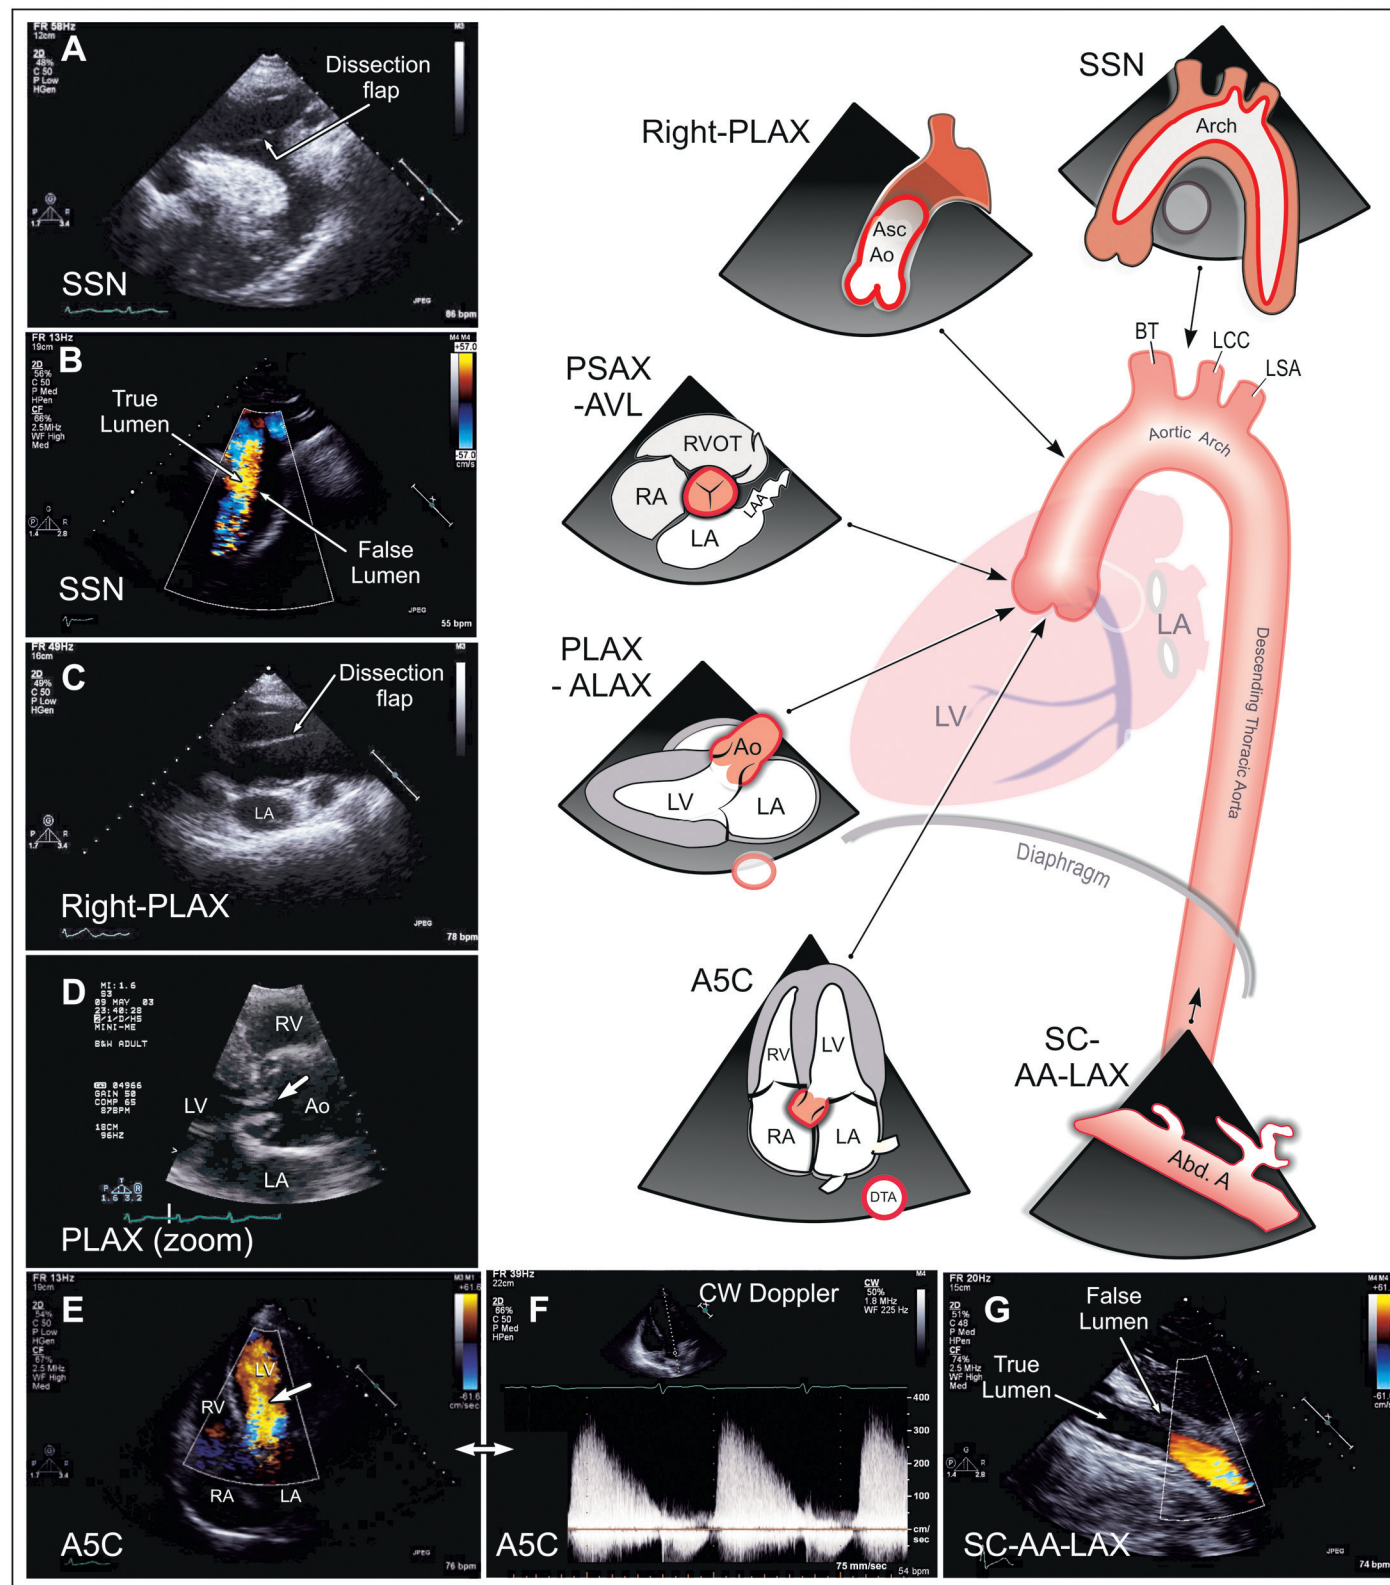

FIGURE 14-70 Transthoracic views of the aorta and examples of acute aortic pathologies from each window. The composite illustrates suprasternal notch (SSN) two-dimensional and color Doppler views of a type A dissection flap that is seen extending into the brachiocephalic artery (**A**, **B**); a type A dissection flap that originates at the level of the aortic sinuses, prolapses through the aortic valve, and also extends into the ascending aorta in the parasternal long-axis (PLAX) view (**C**, **D**); color and spectral Doppler apical five-chamber (A5C) views illustrating the resultant severe aortic insufficiency (**E**, **F**); and an abdominal aortic (AA) type B dissection with a small central true lumen and chronic thrombus in the circumferential false lumen in the subcostal (SC) long-axis (LAX) view (**G**). ALAX = apical long axis; Ao = aorta; AVL = aortic valve level; BT = brachiocephalic trunk; DTA = descending thoracic aorta; LA = left atrium; LAA = left atrial appendage; LCC = left common carotid; LSA = left subclavian artery; LV = left ventricle; RA = right atrium.

FIGURE 14-71 This TEE composite illustrates short- and long-axis views of an intramural hematoma in the ascending aorta (arrow) (A, B); a type A dissection flap that originates at the level of the aortic sinuses, prolapses through the aortic valve (AV), and also extends into the ascending aorta (Asc Ao) (C, D); severe aortic insufficiency resulting from dissection in the same patient (E); long-axis (LAX) and short-axis (SAX) views of partial aortic transection occurring in the descending (Desc) thoracic aorta just distal to the origin of the left subclavian artery as a result of sudden deceleration during a motor vehicle accident (F, G); and long- and short-axis views of a type B aortic dissection flap visualized in the distal descending thoracic aorta (H-J). FL = false lumen; LA = left atrium; LV = left ventricle; ME = midesophageal; RA = right atrium; TL = true lumen; UE = upper esophageal.

the exception of a small area of distal ascending aorta (because of shadowing from the air-filled trachea interposed between the esophagus and the heart). Hence for screening purposes or for serially monitoring a known aortic abnormality for stability, TTE may be sufficient. Higher degrees of suspicion for an acute aortic process or disease extending beyond the TTE windows require TEE evaluation (or alternatively, CT or magnetic resonance angiography [MRA]).

During the standard echocardiographic examination the normal diameter of the aorta should be assessed at the aortic annulus, sinuses of Valsalva, sinotubular junction, and ascending aorta. The upper limit of normal varies with age, sex, and body surface area. More of the ascending aorta can be viewed by moving the transthoracic probe up one interspace, angling the probe more cephalad, or making use of right parasternal windows.

Focal Aortic Pathology

Atherosclerotic plaque can be visualized as irregular, heterogeneous, or echobright calcified foci adherent to the endothelial side of the

lumen. Foci often accumulate at the sinotubular junction and aortic arch. Plaque that is thicker than 5 mm or has mobile or protruding elements has been shown to be at higher risk of being associated with stroke (Fig. 14-72A). *Ulcerated aortic plaque* is thought to be a potential precursor to intramural hematomas (see later). In patients with bicuspid valves, the descending aorta should always be evaluated carefully for signs of narrowing and blood flow acceleration at the isthmus to rule out *aortic coarctation*.

Aortic Emergencies

Aortic aneurysms, technically defined as vessel dilation greater than 50% above the normal diameter of the aorta, may occur anywhere along the course of the aorta (Fig. 14-72B), although they are more common in the abdominal location. Patients with connective tissue diseases such as Marfan syndrome, Loeys-Dietz syndrome, and Ehlers-Danlos syndrome type IV and patients with bicuspid aortic valves are thought to have defects in the elastic and smooth muscle composition of the aorta and hence appear to be prone to the

FIGURE 14-72 Aortic atheroma and aneurysm. **A**, Transesophageal views of complex aortic atheroma in the ascending aorta. In the long-axis view (*left panel*), the atheroma is seen to be irregular and measures up to 1.0 cm in thickness. In the short-axis view (*right panel*), protuberant finger-like atheroma is seen and is independently mobile. **B**, Transthoracic parasternal long-axis (*left*) and subcostal (*right*) views of a large 7-cm-diameter descending thoracoabdominal aortic aneurysm (*dotted arrows* spanning the diameter) compressing the posterior aspect of the left atrium (LA), with diffuse circumferential thick mural thrombus layered within the endocardial borders. Ao root = aortic root; LV = left ventricle.

development of ascending aneurysms (generally defined as an ascending aortic diameter >3.6 cm). Marfan syndrome in particular often affects only the sinuses of Valsalva symmetrically, whereas diameters at the sinotubular junction and ascending aorta are relatively preserved. If the aneurysm involves the ascending aorta, sinuses, and the proximal root all the way to the annulus (termed “aortoannular ectasia”), the resulting incomplete cusp coaptation may cause aortic insufficiency and necessitate valve repair as well. Isolated *sinus of Valsalva aneurysms* are focal dilations that asymmetrically affect only one sinus (most commonly the right, as shown in **Fig. 14-73**), are usually discovered incidentally, and are of unclear cause. Although not considered an acute aortic emergency, there have been case reports of rupture of these aneurysms into the right ventricle, right atrium, and other locations. In contrast to *ascending aneurysms*, most *descending aortic aneurysms* are associated with atherosclerosis. Whereas ascending aneurysms are typically fusiform, abdominal aneurysms may be more irregular, focal, and sacular in shape.

The most common emergency indication for echocardiography in patients with aortic diseases is to detect *aortic dissection*, a tear in the aortic intima that enables blood to force its way between the other layers of the vessel wall. Although it can arise de novo, aortic dissection and rupture are the most feared sequelae of aortic aneurysms and hence share the same causative associations and risk factors, including connective tissue disorders, aortic valve disease (personal or family history), hypertension, and atherosclerosis. **Figures 14-70** and **14-71** show examples of aortic dissections and their

locations and appearance. Recent aortic manipulation—such as cardiac catheterization, cardiac surgical bypass, placement of intra-aortic balloon pumps, and intravascular stenting—is also considered a high-risk condition.⁷⁴ Serious morbidity from compromise of blood flow to the coronary arteries, central nervous system, renal arteries, and other organs may occur, and if the dissection ruptures through all three layers, massive bleeding and death can rapidly ensue. Dissection tends to propagate in antegrade fashion (i.e., from the proximal toward the distal aorta), although retrograde extension may also occur. The mortality rate is high, and surgical treatment has been shown to be the most effective therapy for patients with ascending (DeBakey types I to II or Stanford type A) dissections. Blunt chest trauma, in particular, rapid deceleration injuries (such as in motor vehicle accidents), may cause tears at the ligamentum arteriosum (near the aortic isthmus, just distal to the left subclavian artery), which demarcates a hinge point between the relatively tethered descending thoracic aorta and the more mobile arch and ascending aorta. Tertiary syphilis is now a rare disease in the developed world and can cause *aortitis*, that is, inflammation of the aortic adventitia, weakening of the walls, and subsequent development of descending aortic aneurysms and dissections. Rarely, other systemic arteritides such as giant cell arteritis can also cause aneurysm formation in the ascending aorta.

TTE has somewhat limited sensitivity (59% to 83% for all locations but 78% to 100% in type A dissections) and specificity (63% to 93%) for aortic dissection because of limited views of the abdominal aorta.⁷³ TEE has been shown to have a sensitivity of approximately

FIGURE 14-73 Sinus of Valsalva aneurysm. **A**, TEE long-axis view of a right sinus of Valsalva aneurysm (measuring 2.5×2.8 cm). **B**, TEE short-axis view of the tri-leaflet aortic valve in the open position showing the right sinus aneurysm in cross section. The patient had mild aortic insufficiency.

98% and specificity of 99% to 100%, particularly with respect to ascending dissections. An aortic dissection flap on echocardiography appears as a linear or thin serpiginous tissue plane extending parallel (in the long-axis plane) (**Fig. 14-74A**; see also **Fig. 14-70A, C**) or semicircumferentially (in the short-axis plane) (see **Fig. 14-71C**) to the aortic walls. It represents the intima that has split from the other layers of the aorta. An acute, unthrombosed flap will undulate independently and usually bulge outward from the true lumen in pulsatile fashion during systole. These characteristics can be demonstrated by M-mode and be used to distinguish true disease from reverberation artifact. If color Doppler is used to sweep along the flap, one may occasionally be able to identify the site of the primary tear as a communication between the false and true lumen. The false lumen may be seen to contain more spontaneous echocardiographic contrast or even formed thrombus. By color and spectral Doppler, forward flow in systole can also help identify the true lumen (**Fig. 14-74B, E**). Complications arising from aortic dissection that may be directly imaged by ultrasound include (1) extension of the flap into the coronary arteries with loss of the diastolic-dominant coronary flow by spectral and color Doppler and wall motion abnormality signaling MI; (2) aortic insufficiency (see **Fig. 14-70E, F**); (3) extension of the flap into the carotid arteries (causing stroke) or the innominate or subclavian arteries (see **Fig. 14-70A**); (4) pericardial effusion, which is frequently frank hemopericardium; (5) pleural effusion, which is more common on the left than on the right side; and (6) periaortic hematoma, signifying a leak in the adventitia and impending complete rupture.

There are other aortic emergencies that are less common but equally life-threatening. *Aortic transection* occurs as a result of severe deceleration injury and consists of complete shearing of the aorta at the isthmus with the severed ends of the aorta floating freely within hematoma. This is obviously so lethal that examples are rarely captured on TEE during emergency surgery or endovascular repair, but local containment of blood within the mediastinum can permit a very brief window of survival. A partial transection is shown in **Figure**

14-71F, G. *Aortic intramural hematoma* (see **Fig. 14-71A, B**) is an accumulation of blood that remains contained within the aortic media; it accounts for approximately 5% to 20% of acute aortic syndromes. On echocardiography it appears as a smooth, homogeneously echogenic bulge within the medial layer of aortic wall. It is hypothesized to arise from (1) rupture of a penetrating atherosclerotic ulcer, (2) spontaneous rupture of the vasa vasorum, or more commonly (3) blunt trauma. Intramural hematomas are distinguished from the typically focal, echobright, and irregular plaque in that they lie within the aortic wall and extend smoothly and longitudinally along the aorta. On cross-sectional views it appears as a crescentic or circular area of homogeneous thickening around the central aortic lumen. Unlike dissection, the intimal layer is still intact and is not mobilized, so there is no detectable intimal tear and no blood flow communication with the aortic lumen. If the intramural hematoma is relatively small, additional imaging with CT or MRA may be required to definitively identify the hematoma and distinguish it from the differential diagnoses of plaque or periaortic fat. Intramural hematomas can arise in either ascending or descending locations and may enlarge or progress to frank aortic dissection. Hence the principles of medical and/or surgical management are essentially the same as those for typical aortic dissections.

PULMONARY EMBOLISM (see Chapter 73)

Echocardiography can be extremely useful in the diagnosis and management of acute pulmonary embolism. Although not generally used as the primary diagnostic method for assessing pulmonary embolism, echocardiography provides helpful supportive information to complement other diagnostic tests for this disorder. Thrombi that result in pulmonary embolism generally arise from the deep venous system in the legs, and echocardiography can be used to visualize thrombus in the venous system anywhere from the vena cava through the pulmonary arteries. All potential thrombi in the heart need to be distinguished from other cardiac masses, including myxomas, fibroelastomas, and other cardiac tumors (see **Cardiac Masses**). Thrombi in the pulmonary arteries can generally be visualized to approximately just past the bifurcation with TTE and somewhat further with TEE. Nevertheless, TEE is rarely used as a primary diagnostic modality for pulmonary embolism. The pulmonary artery bifurcation should be carefully assessed from the short-axis views in patients with suspected pulmonary embolism, and it is not uncommon for so-called saddle emboli to become lodged at the bifurcation (**Fig. 14-75**).

The characteristic echocardiographic findings in pulmonary embolism are due in part to the unique physiology of the right ventricle. The normal right ventricle is generally accustomed to low PVR and hence very low afterload, and RV systolic pressure is normally low. In acute pulmonary embolism, PVR rises substantially and abruptly, which results in RV dilation and, in severe cases, failure. Thus RV dilation is the echocardiographic hallmark of pulmonary embolism. It is best visualized on the apical four-chamber view, where classic findings include RV diameter greater than LV diameter and relatively normal LV function with a small underfilled left ventricle. A distinctive regional wall motion abnormality has been recognized in acute pulmonary embolism in which the free RV midwall becomes dyskinetic, with relative sparing of the apex and base. This pattern, known as the McConnell sign (**Fig. 14-76**), is associated with very high specificity and is generally seen only in conditions in which PVR increases abruptly.⁷⁵ Both RV dilation and RV regional dysfunction will be less apparent in patients in whom PVR has been elevated for a longer period. In these patients the right ventricle hypertrophies, pulmonary pressure will ultimately rise, and the right ventricle may not show evidence of dilation or dysfunction in the setting of pulmonary embolism. Thus these echocardiographic findings are less likely to be useful in patients with longstanding pulmonary hypertension, chronic obstructive pulmonary disease (COPD), or chronic thromboembolic disease in which pulmonary hypertension has been longstanding.

In patients without a previous history of pulmonary hypertension, pulmonary pressure is not generally elevated in acute pulmonary embolism, and TR velocity will be relatively normal and rarely higher than 3 meters/sec. Patients with preexisting pulmonary vascular disease, however, may have increased TR velocity consistent with elevated pulmonary systolic pressure. The presence of RV dilation or dysfunction in acute pulmonary embolism has important prognostic significance because these patients have been shown to have increased risk for short-term mortality. Echocardiography can be used to assess

FIGURE 14-74 Aortic dissection demonstrating true and false lumens. **A**, TTE high parasternal long-axis view of a type A aortic dissection. The linear dissection flap is indicated by the arrow. FL = false lumen; TL = true lumen. **B**, TTE view at the same level with color flow Doppler illustrating brisk and turbulent color flow within the true lumen. **C**, M-mode illustrating systolic pulsation of the dissection flap (arrow) outward from the true aortic lumen. **D**, Low-velocity spectral Doppler flow without clear cyclical variation in the false lumen. **E**, Systolic forward high-velocity spectral Doppler flow in the true lumen. **F**, Transesophageal short-axis view of the ascending aorta in a different type A dissection case demonstrating spontaneous echocardiographic contrast in the false (larger) lumen and brisk systolic flow in the true (smaller) lumen by color Doppler.

FIGURE 14-75 Saddle embolus at the bifurcation of the pulmonary artery (arrow).

FIGURE 14-76 Regional right ventricular dysfunction (McConnell sign) in acute pulmonary embolism. The right ventricle (RV) is enlarged and right ventricular regional function is abnormal, with dyskinesia of the midwall region and relative sparing of the apex and base. TR is usually present. LA = left atrium; LV = left ventricle; RA = right atrium.

response to therapy for acute pulmonary embolism. Improvement in RV function can be seen within several days of successful treatment (such as embolectomy or thrombolysis) of pulmonary embolism. Myocardial strain imaging may have some usefulness in RV assessment and has been shown to have substantially abnormal findings in patients with acute pulmonary embolism.

INFECTIVE ENDOCARDITIS (see Chapter 64)

Echocardiography has a first-line role in the detection, evaluation, and management of endocarditis. American College of Cardiology/American Heart Association class 1 indications for echocardiography are for the following settings: (1) in patients with suspected endocarditis (with or without positive blood cultures) to detect valvular vegetations; (2) in cases of known infective endocarditis to evaluate for valve lesions such as regurgitation and to assess for

complications such as abscess and intracardiac shunts; (3) to reevaluate patients with known endocarditis who have high-risk features such as a virulent organism, clinical deterioration, persistent or recurrent fever or bacteremia, and a new murmur; and (4) in symptomatic patients with a nondiagnostic TTE or prosthetic valves, for which TEE is likely to have higher sensitivity for both vegetations and complications.⁷⁶

Infective endocarditis is definitively diagnosed by culture or pathologic examination of a vegetation (in situ or embolized) or intracardiac abscess. However, many cases are diagnosed on clinical grounds by using the modified Duke criteria as a guideline. The first criterion is positive blood cultures consistent with infective endocarditis. The second major criterion is an echocardiogram demonstrating (1) a vegetation (**Fig. 14-77A, B**; see also Figs. 64-1 and 64-2) (i.e., an oscillating intracardiac mass on a valve, in the path of a regurgitant jet, or on implanted material) in the absence of an alternative

FIGURE 14-77 Echocardiography in endocarditis. **A**, Vegetation (arrow) on the left atrial aspect of a rheumatic mitral valve (left panel) with color Doppler demonstration of a second noncentral jet of MR at the base of the leaflet and vegetation indicative of leaflet perforation (right panel). **B**, Vegetation (arrow) on the right atrial aspect of the tricuspid valve on a TEE long-axis view. An additional vegetation (arrow) in the SVC associated with a previous indwelling catheter is noted, and the eustachian valve was also infected in this patient with a history of intravenous drug abuse. **C**, Perivalvular abscess (arrow) as indicated by the crescentic echolucent area with thickening from the 11 to the 1 o'clock position on short-axis (left panel) and long-axis (middle panel) TEE views anterior to the annulus of a bicuspid aortic valve (open in systole), also visualized on the three-dimensional TEE view (right panel). **D**, Ringlike abscess around the annulus of a bioprosthetic aortic valve as seen on a short-axis TEE view (left panel). This causes dehiscence of the valve, as seen on long-axis TEE views (middle and right panels) in which it rocks forward in systole and prolapses into the LVOT in diastole. Ao = aorta; LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

anatomic explanation, (2) an abscess (Fig. 14-77C), or (3) new partial dehiscence of a prosthetic valve (Fig. 14-77D).⁷⁶ The sensitivity of TTE ranges up to 63%, with a specificity close to 100%. The suboptimal sensitivity is often due to physical imaging factors causing poor image quality and acoustic shadowing and is also dependent on the size of the vegetation. Because of its higher two-dimensional resolution and different windows, TEE has much higher sensitivity (94% to 100%) and is especially advantageous in assessing prosthetic valves and diagnosing abscesses. Hence a reasonable diagnostic approach is to use TTE as the first-line screening tool; if this is nondiagnostic, one may turn to TEE if clinical suspicion for endocarditis is high, such as if the patient has a prosthetic valve or predisposing condition, clinical features suspicious for a complicated endocarditis, and/or a potential indication for cardiac surgery.⁷⁷

Vegetations appear as discrete echogenic masses that are adherent to but distinct from the leaflet itself. A typical mitral vegetation is shown in Figure 14-77A (see also Fig. 64-2). Characteristics of vegetations that aid in distinguishing them from other masses include *localization, texture, motion, shape, and associated abnormalities*. Vegetations can be located on the upstream, or low-pressure, side of the valve, be located in the path of any regurgitant bloodstream (i.e., the atrial aspect of atrioventricular valves and the ventricular aspect of semilunar valves), and less commonly, be attached to the periphery of septal defects, on chordae, and on the mural endocardium. The *echodensity* of a vegetation is usually similar to that of myocardium, although advanced vegetations can be inhomogeneous, a finding indicative of liquefaction (which is echolucent) or calcification (which is echodense or bright). Independent *motion* of vegetations is frequently oscillating or erratic. Large vegetations can prolapse into the upstream chamber and create a “ball-and-chain” effect that causes leaflet flail and regurgitation. Vegetations vary tremendously in *shape* but often appear as compact multilobulated and/or pedunculated, amorphous, and friable agglomerations in comparison to tumor tissue or thrombus. The vegetations can extend some distance from the valve to which it is tethered and may occur in multiples on the same or different valves. *Associated abnormalities* such as regurgitation, abscesses, and intracardiac channels can accompany advanced endocarditis. There are no distinguishing characteristics that are organism specific, although staphylococcal infections (particularly methicillin-resistant *Staphylococcus aureus* and *Staphylococcus lugdunensis*) tend to be more destructive and form abscesses, and fungal infections are often impressively large and dendritic in appearance.⁷⁸

Vegetations devoid of microorganisms are the hallmark of *noninfectious endocarditis*, also termed nonbacterial thrombotic or marantic endocarditis (see Chapter 64). The typical lesions are small (1 to 5 mm), verrucous, nondestructive nodules that adhere to the upstream side of the valve (typically mitral or aortic) along the line of closure and contain only cellular and fibrin elements. These aseptic lesions are seen in up to 43% of patients with systemic lupus erythematosus (SLE) and 29% of those with antiphospholipid syndrome (APS), in whom they are frequently manifested as cerebral embolization. They also occur in patients with advanced neoplasms, sepsis, and prothrombotic tendencies in association with clinical features indistinguishable from those of typical infective endocarditis (see *Systemic Diseases and Echocardiography*, later).⁷⁹

Of note, the presence of preexisting thickening and/or degenerative changes in leaflets can render the diagnosis challenging. On occasion, myxomatous leaflets, ruptured chords, calcified structures, and fibrin strands can either mask or mimic a vegetation. Papillary fibroelastomas and thrombi can resemble valvular vegetations. In these circumstances, clinical correlation with other Duke diagnostic criteria is important. Comparison with previous echocardiograms should also be taken into account; a stable finding over a period of years is unlikely to represent a vegetation. Use of TEE for higher-resolution images is often helpful, particularly if a cardiac device is involved or a complication is suspected.⁸⁰

Among patients with endocarditis, 66% to 75% appear to have risk factors for infection, and echocardiography should be used to scrutinize the relevant structures at risk especially carefully. Patients

with prosthetic valves (see Fig. 64-3), complex cyanotic congenital heart disease or surgical systemic-pulmonary shunts, bicuspid aortic valves, rheumatic heart disease, and mitral valve prolapse are thought to be at higher risk. Previous endocarditis and intravenous drug abuse are obviously strong predisposing factors, with the tricuspid and pulmonary valves being exposed to bacteremic seeding in the latter group. Other intracardiac structures that are prone to infection, usually at the time of placement or access, include defibrillator/pacemaker wires and chronic indwelling intravenous catheters, particularly when used for total parenteral nutrition or hemodialysis in immunocompromised patients. Echocardiographic characteristics associated with a poorer prognosis and embolization include vegetation size greater than 1.0 cm (which confers a 2.5-fold higher risk for embolization, especially if on the mitral valve), increasing size of the vegetation over time despite therapy, very mobile vegetation, and perivalvular abscess (which is more frequent with prosthetic valves [see Fig. 64-4] and increases mortality by 2-fold^{80,81}).

The natural history of vegetations after medical therapy is of interest because most will still be apparent on follow-up echocardiography in 1 to 2 months even after successful medical treatment. Approximately half will become more echodense over time. These observations probably reflect the varied components of the vegetation, which include not only bacteria but also inflammatory cells, fibroblasts, and extracellular matrix. Growth of a vegetation over time and increasing valvular regurgitation are poor prognostic signs. However, the mere persistence of vegetations in the absence of symptoms or positive blood cultures is not associated with increased clinical complications. Thus treatment of infective endocarditis should not be guided by the echocardiographic morphology of the vegetation over time but by clinical response to therapy.

Role of Echocardiography in Surgery for Endocarditis

If left untreated, infective vegetations are destructive via pathways that are apparent on echocardiograms and ECGs and by clinical sequelae. If present, these vegetations are indications for surgery, particularly if recalcitrant to medical therapy. Indications include (1) embolism to the coronary arteries, brain, lungs, spleen, kidney, or extremities; (2) severe valvular regurgitation and heart failure secondary to leaflet malcoaptation, perforations, or flail; (3) abscess, which may invade the cardiac conduction system; (4) mycotic aneurysms of vessels and valves; (5) pseudoaneurysms or fistulas of the heart; and (6) suppurative or hemorrhagic pericarditis.

Typical paravalvular extension patterns can be detected on echocardiograms (and ECGs). On the *aortic valve*, involvement of the right cusp can lead to necrosis of the membranous interventricular septum, aneurysm of the right sinus of Valsalva, and valve dehiscence. Embolization into the RCA can also occur and cause MI. Involvement of the left cusp can affect the intervalvular fibrous curtain and extend to infect the base of the anterior mitral valve leaflet. There is also the potential to form an aortic-to-LVOT fistula, or paravalvular leak. Involvement of the noncoronary cusp can extend to the posterior interventricular septum, where the His conduction fibers are located, which can lead to the development of an intra- or infra-Hisian block (third-degree atrioventricular block) or bundle branch block.

Severe infection of the *mitral valve* less commonly leads to conduction disturbances. Although first- or second-degree atrioventricular block can occur, supraventricular tachycardias are more common. *Tricuspid valve* infection can extend to involve the tricuspid annulus and eustachian valves (Fig. 14-77B), seed the pulmonic valve, and causes septic pulmonary emboli in 25% to 80% of cases.⁸⁰

SYSTEMIC DISEASES AND ECHOCARDIOGRAPHY

Aside from conditions that directly affect the heart itself, echocardiography can be used to detect and monitor the secondary effects of systemic disease on the heart. Uncontrolled hypertension causes

symmetrically increased wall thickness and LV hypertrophy in association with LA enlargement and diastolic dysfunction. Renal disease causes early calcification of the valves and potentially uremic pericardial effusions. Hypothyroidism can be associated with a myxedematous pericardial effusion. COPD can cause conspicuous right-sided heart enlargement, RV hypertrophy, elevated TR velocity, and a prominent pericardial fat pad secondary to corticosteroid treatment.

Echocardiography can also be helpful in assessment of diseases that tend to infiltrate and affect all layers of the heart, such as amyloidosis (see earlier), which is notorious for causing restrictive cardiomyopathy, but also valvular thickening, atrial mural deposits, and pericardial effusions. Granulomatous diseases such as sarcoidosis (Fig. e14-12) can cause a focal myocarditis with granulomas, which results in very localized areas of akinesis in a noncoronary distribution. Pericarditis, valvulitis, and coronary and aortic arteritis have also been reported with Wegener granulomatosis. Although histologically scleroderma is known to cause direct myocardial fibrosis, on echocardiography this becomes apparent in only a minority of patients, usually late in the course of disease. The most common echocardiographic abnormalities in scleroderma are elevated RV systolic pressure, RV dilation, and pericardial effusion, as well as LA enlargement and diastolic dysfunction.

Other diseases that have echocardiographic manifestations include human immunodeficiency (HIV) infection (see Chapter 70), in which the most common echocardiographic abnormalities are pericardial effusion (seen in up to 25% of cases), but also HIV-related pulmonary hypertension and cardiac lymphomas. With an aging HIV/acquired immunodeficiency syndrome (AIDS) population, there appears to be an increasing incidence of cardiomyopathy as well. Formerly, such cases were less prevalent, but the prolonged duration of HIV infection and newer highly active antiretroviral therapy (HAART) regimens may contribute both directly and indirectly (via lipodystrophic effects, chronic inflammation, and accelerated CAD) to cardiomyopathy.^{82,83}

Similarly, even when cancers spare the heart, the radiation and chemotherapy regimens used to attack the neoplasms can have cardiac effects (see Chapter 69). The early detection of cardiomyopathy in patients who receive anthracycline therapy allows modification of the chemotherapy protocol before irreversible damage occurs. Although it is common to screen for this by quantitating LVEF, strain rate imaging may turn out to be a more sensitive and earlier predictor of cardiotoxicity.⁸⁴ Survivors of Hodgkin disease frequently have early thickening and stenosis of the aortic valves, as well as accelerated CAD.

Several conditions predispose to valvular abnormalities (see also Valvular Heart Disease, earlier). Rheumatic carditis and its sequelae are well-known historical examples and are still a significant cause of heart disease in developing nations (see Chapter 83). More than 50% of patients with carcinoid tumors have cardiac involvement in which plaque-like deposits build up on the right-sided heart valves (typically the ventricular aspect of

the tricuspid valve and the arterial aspect of the pulmonic valve). This causes a characteristic retracted and fixed appearance of the tricuspid and pulmonary leaflets and a combination of valvular stenosis and regurgitation (see Fig. 14-54). Patients with cardiac involvement have markedly worse median survival than do those without cardiac manifestations. The hematologic malignancies and any thrombophilic state (e.g., sepsis, disseminated intravascular coagulation, SLE, APS) can cause nonbacterial marantic endocarditis in which the sterile vegetations and fibrin strands undergo frequent cycles of growth and subsequent fragmentation and embolization, with associated valvulitis and leaflet destruction. The systemic vasculitides such as Takayasu arteritis and Behçet disease are notable causes of aortic regurgitation, particularly in younger patients.⁸⁵

PULMONARY HYPERTENSION (see Chapter 74)

Echocardiography is vital to narrowing down the differential diagnosis of other conditions that cause pulmonary hypertension. In the absence of known pulmonary disease, the presence of an enlarged right side of the heart with a normal-appearing left ventricle (Fig. 14-78) should prompt a search for secondary causes of pulmonary hypertension. Causes that are detectable by echocardiography include intracardiac shunts with atrial septal defects (ASDs) (and most shunts above the tricuspid valve), mitral stenosis, and occasionally pulmonary thromboembolism. Noncardiac causes include mixed connective tissue disease, systemic sclerosis, SLE, and sickle cell disease, in which pulmonary hypertension is an important cause

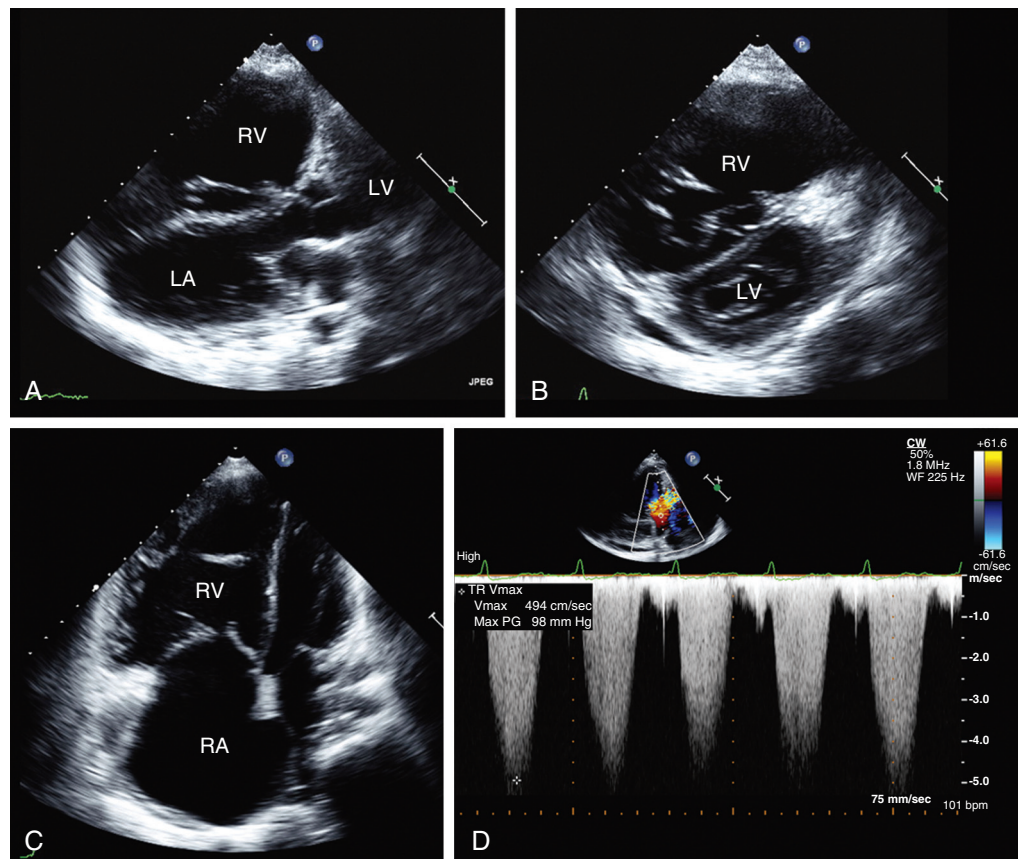

FIGURE 14-78 Pulmonary hypertension secondary to chronic thromboembolic disease. **A**, Parasternal long-axis view illustrating a small left ventricular cavity and enlarged RVOT. **B**, Parasternal short-axis view demonstrating the D-shaped left ventricular cavity caused by systolic and diastolic septal flattening from pancyclic elevated right ventricular pressure. **C**, Apical four-chamber view. Note the dilated right atrium (RA) and tricuspid annulus with incomplete closure of the tricuspid valve, as well as leftward distension of the interatrial septum. **D**, Severe TR with an elevated TR velocity corresponding to a calculated right ventricular systolic pressure of 98 mm Hg plus right atrial pressure. The upslope of the tricuspid regurgitant jet is slow, indicative of poor right ventricular contractility. LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

FIGURE e14-12 Sarcoidosis. **A**, Apical four-chamber view illustrating the right-sided heart enlargement (actually larger than the left ventricle and containing a pacemaker wire) and the septal focal wall motion abnormalities in the left ventricle (“scalping”) typically seen in sarcoid heart disease. See accompanying video. **B**, Apical two-chamber view illustrating very focal areas of thinning and akinesis (*arrows*) in the inferior LV wall because of sarcoid granulomas and/or myocardial scarring.

of morbidity and mortality. In general, the indices of pulmonary arterial systolic pressure and right-sided heart failure (e.g., interventricular septal flattening, TAPSE, FAC, and other indices) have been shown to be predictors of mortality in patients with diverse causes of both primary and secondary hypertension.^{86,87}

Two-dimensional echocardiographic findings in patients with pulmonary hypertension include flattening of the interventricular septum (first in diastole and subsequently, as pressure rises further, in systole), dilation of the pulmonary artery, RV hypertrophy, RV dilation, and ultimately RV dysfunction. Typical Doppler findings include elevated TR velocity, enlargement of the right atrium, dilation of the IVC and hepatic veins, and loss of pulsatility of the IVC.

Pulmonary pressure can be assessed relatively accurately by using the Bernoulli equation to estimate the pressure gradient between the right ventricle and the right atrium. If TR is not present or the TR jet is acquired off-axis, this measurement will be impossible to make or will underestimate the severity of pulmonary hypertension. In addition to assessment of pulmonary pressure, PVR can be measured noninvasively by using a validated formula⁸⁸:

$$PVR_{\text{ECHO}} = 0.618 + 10.006 \times \text{TRV} / \text{TVI}_{\text{RVOT}}$$

where TRV = TR velocity and TVI_{RVOT} represents the RVOT VTI. Assessment of RV size and function is essential in pulmonary hypertension. RV FAC, TAPSE, RV Tei index, and tricuspid annular systolic velocity (TAS') are typically used to assess RV function in patients with pulmonary hypertension.⁸⁹ Myocardial strain imaging of the right ventricle may prove useful in assessment of RV function in patients with pulmonary hypertension.

There are several distinguishing features between the echocardiographic findings of pulmonary hypertension and acute pulmonary embolism. Unless the pulmonary embolism is chronic or a patient with acute pulmonary embolism has longstanding thromboembolic disease that has resulted in an elevation in pulmonary pressure, acute pulmonary embolism will not usually be associated with RV hypertrophy, elevation in pulmonary pressure, or flattening of the interventricular septum in systole. In addition, the regional RV dysfunction in acute pulmonary embolism usually spares the apex, whereas apical RV function generally appears reduced along with the rest of the ventricle in pulmonary hypertension.

CARDIAC MASSES

Cardiac tumors are relatively rare (ranging from an incidence of 1% to 2% in general autopsy series but up to 4% to 8% in cancer patient autopsies), and hence routine screening is not performed. Among primary tumors of the heart, it is estimated that up to 90% or more are detected incidentally and three quarters are benign. The location of an intracardiac or extracardiac mass—in the context of the patient's age, clinical findings, and comorbid conditions—is often an indication of the type of tumor, with the morphologic features often playing only a secondary role in identification (Table 14-12).⁹⁰

Nonetheless, the overall appearance of the mass (with respect to size, solid versus cystic, shape, degree of independent mobility, and fragility), its attachments, and the extent of myocardial, endocardial, or pericardial invasion can offer clues to its nature. Calcified or fibrotic areas appear echobright, whereas cystic degeneration causes echolucent foci on echocardiography. Obstruction to caval or valvular inflow will cause increases in peak spectral Doppler velocities, often with a mosaic color Doppler pattern signifying turbulent flow. Mitral stenosis and MR caused by an LA myxoma prolapsing across the mitral valve is a classic example (Fig. 14-79). The echocardiographic appearance of this entity is so pathognomonic that usually no further workup is required before surgical resection. Similarly, papillary fibroelastomas occur so characteristically on the aortic and mitral valves and are so commonly seen as filamentous or amorphous growths that shimmer, undulate, and prolapse that further assessment may not be required before surgery, although they may be difficult to differentiate from highly mobile Lambl excrescences (Fig. 14-80).

In selected cases, to refine the diagnostic possibilities, intravenous echocardiographic contrast material may be used to determine whether a tumor hyperenhances. Hyperenhancement indicates that the mass is neovascularized and hence more likely to be malignant as opposed to being a benign stromal tumor or thrombus.⁹¹ One can also use three-dimensional echocardiography to better illustrate the overall size, location, and attachments of intracavitary masses in real time. In addition, echocardiography offers a convenient way to monitor for recurrence, growth, or adverse sequelae after excision or treatment.

Common Primary Tumors

Myxoma accounts for more than 50% of primary cardiac tumors in adults, followed by lipomas and papillary fibroelastomas. It is a primary benign tumor believed to arise from mesenchymal (endocardial) cells. It typically arises in the left atrium (75% of cases, with the other 20% occurring in the right atrium and 5% in the ventricles) and is attached to the interatrial septum near the fossa ovalis by a stalklike pedicle. Attachments to the mitral valve have been described in a small percentage of cases. Grossly and by echocardiography, myxomas frequently appear as a gelatinous, compact mass, but there is a spectrum of morphologies—smaller tumors tend to be more papillary or villous and are friable and hence prone to embolize; larger tumors have a smoother, globular, or grape cluster-like appearance and can grow large enough to fill the left atrium and cause both mitral stenosis and a renowned tumor “plop” on auscultation as the mass prolapses into the left ventricle in diastole (see Fig. 14-79).⁹²

In adults, *papillary fibroelastomas* are the next most common cardiac benign tumors and the most common valvular tumor. Most (<80%) are found on left-sided (aortic or mitral) valves, although any valve may be affected, and 9% are manifested as multiple lesions. Pathologists usually classify fibroelastomas as an advanced or more florid form of Lambl excrescences, which are degenerative changes in the valves. They have a tendency to appear on either side of the aortic valve or on the atrial side of the mitral valve. Less frequently, they have also been known to arise on mitral chordae or papillary muscles. On echocardiography they appear round, oval, or irregular in shape and homogeneous in texture (Fig. 14-80). Almost half have a short stalk, which confers more mobility. They are found most frequently in older adults as solitary lesions (<10% occur as multiple lesions), and shedding of the threadlike elements and/or associated clot accounts for their frequent manifestation as embolization (transient ischemic attack or stroke, angina, or sudden death).^{90,93}

Lipomas are encapsulated collections of benign fat cells that tend to occur in subepicardial or subendocardial locations and may grow into the pericardial space. Although benign, usually discovered incidentally, and easily distinguished by cardiac magnetic resonance (CMR) characteristics (see Chapter 17), these tumors tend to increase progressively and can cause mass effect, heart block, or tachyarrhythmias. On imaging, lipomas can be difficult to distinguish from *lipomatous hypertrophy of the interatrial septum*, which is a normal finding, particularly in elderly or obese patients (see the later section on pseudotumors). However, lipomatous hypertrophy is technically hyperplasia of epicardial adipocytes within the groove between the LA and RA walls and inferior pyramidal space, which spares the fossa ovalis and produces a characteristic dumbbell-shaped mass. Although lipomatous hypertrophy is unencapsulated and may reach an impressive thickness (1 to 2 cm), if the location is typical and no associated atrial arrhythmias or caval obstruction are present, no treatment is indicated.⁹⁴

Pericardial cysts are benign fluid-filled tumors of the parietal pericardium and are thought to be a congenital abnormality.⁹⁵ They may be solitary or multilobular, and some have been documented to grow to massive (>20 cm) size. They account for approximately 20% of benign primary cardiac masses (overall incidence of 1 in 10,000) and commonly occur near the cardiophrenic borders (right more frequently than the left). This gives the appearance of cardiomegaly on chest radiographs and forms an encapsulated echolucent area on echocardiography.⁹⁶ Of known cases, 75% are asymptomatic. However, if large they may cause atypical chest pain, breathlessness, atrial fibrillation, persistent cough, or compressive problems such as RVOT obstruction. Rare cases of cardiac tamponade secondary to intrapericardial rupture and hemorrhage have been reported.

Rhabdomyomas are the most common primary cardiac neoplasm in children and are usually found during the first year of life. They tend to be solid intramyocardial lesions containing striated myocyte fibers, and 90% occur as multiple tumors. Although most patients are asymptomatic, larger tumors have been known to cause arrhythmias,

TABLE 14-12 Site-Specific Differential Diagnosis of Cardiac Tumors

ONCOLOGIC		ALSO CONSIDER NON-NEOPLASTIC MASSES	NORMAL OR VARIANT STRUCTURES
Left atrium	Myxoma Bronchogenic carcinoma Sarcoma (involving the wall/pericardium) Hemangioma Paraganglioma	Thrombus Endocardial blood cyst	Lipomatous hypertrophy of the interatrial septum External compression (by hernia, thoracic aorta, bezoar) Echocardiographic artifact: pulmonary vein/atrial wall reflections (so-called Coumadin ridge) Appendage pectinate muscles Atrial suture anastomosis after heart transplantation Inverted LA appendage (postoperative) LA chord
Right atrium	Myxoma Nephroblastoma, renal cell cancer Hepatocellular carcinoma Sarcoma (angiosarcoma) Paraganglioma Adrenal tumors	Thrombus (deep venous or in situ) or fibrin casts (of previous indwelling catheter/wire) Vegetation (on pacer/ICD wires) Lipomatous hypertrophy of the interatrial septum	Eustachian valve Chiari network Crista terminalis Interatrial septal aneurysm Pectus excavatum
Left ventricle	Rhabdomyoma (often multiple) Fibroma Hamartomas Purkinje cell tumors	Thrombus Apical hypertrophic cardiomyopathy Subaortic membrane	Calcified or multilobed papillary muscles Redundant mitral chordae Trabeculations, false tendons Focal upper septal hypertrophy Swirling from inhomogeneous intravenous echocardiographic contrast distribution
Right ventricle	Rhabdomyoma Fibroma	Thrombus	Redundant tricuspid chordae Moderator band
Valves/annuli	Papillary fibroelastoma Myxoma Hamartoma Lipomatous tumor	Lambl excrescences Focal or caseous mitral annular calcification Vegetation Marantic endocarditis Thrombus (especially on prosthetics) Pannus (especially on prosthetics) Abscess Blood cyst Rheumatoid nodule	Nodules of Arantius Myxomatous/degenerative changes Pannus, loose suture, biogluue or pledgets around prosthetic valves
Pericardium	Malignant involvement from lung, breast, lymphoma/leukemia, gastrointestinal tract melanoma Mesothelioma Primary: spindle cell tumor, fibrous tumors, lipoma, liposarcoma, teratoma Paraganglioma	Pericardial or bronchogenic cyst Rheumatoid nodule	Epicardial or mediastinal fat Pectus excavatum Atelectatic lung or fibrin in pleural/peritoneal spaces Vascular pseudoaneurysm Thymus (in infants)

ICD = implantable cardioverter-defibrillator.

Modified from Wu J: Cardiac tumors and masses. In Stergiopoulos K, Brown DL (eds): Evidence-Based Cardiology Consult. Springer Science + Business Media, Inc., 2014.

LVOT obstruction, and heart failure. Half the cases are associated with tuberous sclerosis. Most regress spontaneously, and overall these tumors are rare in young adults.⁹⁰

Fibromas are the second most common pediatric cardiac neoplasm. They arise in the ventricular myocardial layer, are five times more common in the left ventricle, and consist of solid tumors containing fibroblasts. These tumors often occur in the LV septum or free wall, where they can become quite large and develop calcific foci. Unlike rhabdomyomas, fibromas do not spontaneously regress and may grow to a size that obliterates the heart chamber, interferes with valvular function, or causes arrhythmia and necessitates surgical resection.⁹²

Secondary Tumors

Secondary cardiac tumors outnumber primary ones by 20 to 40 to 1. In principle, any malignant tumor may metastasize to the heart. The most common site of involvement is the pericardium, with invasion of the myocardium seen next in frequency.⁹⁷

Pericardial involvement in cancers may arise from direct invasion of tumor from adjacent lung or mediastinum (e.g., mesothelioma or lymphoma), or there may be more diffuse involvement and effusive/

constrictive changes. The most frequent sources of malignant pericardial disease are lung cancer, lymphoma/leukemia, and breast cancer because of their relatively high prevalence,⁹⁸ with some worldwide variability. Of all malignancies, melanoma has the highest predilection to metastasize to the heart and pericardium. It is common for cardiac metastases of any source to be small and multiple or else cause effusion or diffuse thickening of the pericardium. However, bulky large solitary tumor lesions may also occur.

Secondary tumors may also invade the heart by direct extension⁹⁰; renal cell carcinoma, Wilms tumor, uterine leiomyosarcoma, hepatomas, and adrenal tumors can be detected extending into the right atrium via the IVC on echocardiography. Bronchogenic carcinomas can invade the left atrium via the pulmonary veins. Lymphatic and hematogenous routes are also pathways to the heart. The location and mass effect of the metastases tend to determine the patient's symptomatology rather than the histologic type.

Alternative Diagnoses

Pseudoneoplasms. With the abundance of cardiac imaging being performed by various modalities, it is inevitable that normal or slight variants of normal structures, degenerative or acquired lesions, and

noncancerous masses may be detected. The onus is on the cardiologist or radiologist to distinguish between the following entities (listed in Table 14-12) and a true neoplasm.

Intracardiac Thrombus

Masses such as thrombi and vegetations have obvious clinical implications. On echocardiography, formed thrombi appear relatively homogeneous in echodensity and have a gel-like or deformable appearance (Fig. 14-81B). Old thrombi may have more echobright regions and a compact immobile or laminated appearance (see Fig. 14-32A). Clues that a mass is actually a thrombus include presence in areas of stasis (e.g., the tip of the LA appendage or within an LV

aneurysm), “wisps” of spontaneous echocardiographic contrast associated with the surface (Fig. 14-81A), and associated predisposing cardiac conditions, including mitral stenosis, prosthetic valves, cardiomyopathy, aneurysms of any chamber, or atrial fibrillation. Rope-like vacillating masses in the right side of the heart often represent thromboemboli from the deep venous system (Fig. 14-82), in which case the IVC, as well as the pulmonary arteries, should be inspected for portions of the same clot. With anticoagulation, intracardiac thrombi frequently regress or remain stable.

The presence of LV aneurysms or severe dilated cardiomyopathy should always prompt vigilance for thrombi. Conversely, it would be highly unusual for a thrombus to form in an area with normal wall

FIGURE 14-81 Spontaneous echocardiographic contrast and left atrial appendage thrombus. **A**, Zoomed TEE view of spontaneous echocardiographic contrast in the left atrial appendage in a patient with a bileaflet mechanical mitral prosthesis who was subtherapeutic with warfarin treatment. **B**, TEE view of organized thrombus (arrow) in the left atrial appendage in a patient following mitral annuloplasty. LA = left atrium; LV = left ventricle.

FIGURE 14-82 Thromboembolus in the right atrium (RA). The arrow indicates a mass representing a serpentine-like clot “cast” in the deep veins of the lower extremities that has embolized to the RA. Note the right-sided heart dilation and hypokinesis, clues indicating that a significant acute pulmonary embolus has also occurred. RV = right ventricle.

motion. Use of a high-frequency (7 or 8 MHz) probe to focus on the cardiac apex, angling it at unconventional views or foreshortening as needed, can better define thrombus versus myocardium and myocardial bands and will also decrease noise and reverberation artifact. Ultrasound contrast enhancement is often useful when endocardial border definition is poor.

TEE, with its higher resolution and proximity to the base of the heart, is likely to be useful for ruling out intracardiac thrombi (or other sources of emboli, such as atheroma or vegetation) when no identifiable source is found after imaging the head and neck arteries and the heart by TTE. An embolic stroke or unusually high transvalvular gradients in a patient with a mechanical (or even bioprosthetic) valve should prompt referral for TEE, contingent on the assumption that the findings on TTE were nondiagnostic and that they would alter management. TEE is also frequently used to facilitate the decision to anticoagulate, cardiovert, or perform radiofrequency ablation of a tachyarrhythmia, particularly in high-risk patients (i.e., those with the predisposing cardiac conditions mentioned earlier or those found to be underanticoagulated before a planned procedure). TEE should be performed before percutaneous mitral valvuloplasty for rheumatic

mitral stenosis to rule out LA thrombus (as well as to better define the mitral anatomy and degree of regurgitation) and thus avert potentially catastrophic complications.

Vegetations

Vegetations tend to arise on the upstream side of valves or at areas of flow turbulence. Valves with degenerative changes, prosthetic valves, and indwelling catheters or pacemaker/defibrillator wires are a well-recognized nidus for infection. Thick, immobile, heaped-up irregular masses affixed to the annuli of older prosthetic valves may represent pannus (fibrovascular granulation tissue). For both thrombi and vegetations, the larger and/or highly mobile masses that threaten the pulmonary, systemic, or cerebral circulation with embolization or cause severe valvular dysfunction may compel emergency surgical resection (see Endocarditis).

Normal Variants and Artifacts

Normal or mild variants of normal structure have also been mistaken for neoplasms on echocardiography. The most common errors are mistaking lipomatous hypertrophy, upper septal hypertrophy, redundant mitral chord or prominent/multilobed papillary muscle, interatrial septal aneurysm, or pericardial fat for a mass.^{90,92} Degenerative changes such as valvular calcification or external compression of chambers of the heart by adjacent structures (e.g., from an esophageal hernia indenting the posterior wall of the left atrium) can give the appearance of a large mass when viewed in only one plane. Knowledge of the typical appearance of these abnormalities, use of echocardiographic contrast material, and careful tilting of the transducer plane to track the boundaries and attachments of these entities can reveal their true nature.

CONGENITAL HEART DISEASE IN ADULTS (see Chapter 62)

Echocardiography plays a critical role in the evaluation and management of both children and adults with congenital heart disease. Consequently, this section focuses on the role of echocardiography in diagnosing common shunts (ASDs and VSDs), as well as transposition of the great vessels and tetralogy of Fallot, complex lesions that may be seen by cardiologists caring for adults. The use of echocardiography for the selection and implantation of ASD closure devices is also covered.

Atrial Septal Defect

ASDs account for approximately 10% of all congenital heart disease and 20% to 40% of congenital heart disease occurring in adulthood.

It is not uncommon for the initial diagnosis of ASD to be made at the time of an echocardiogram performed for nonspecific symptoms or one performed because of a heart murmur in an asymptomatic individual.

General Imaging Principles

The anatomic classification of ASDs is shown in **Figure 14-83**. Although secundum defects are often isolated anomalies, ASDs of other types are frequently associated with other structural anomalies, and multiple ASDs may be encountered in the same patient. Echocardiography is the most widely used modality for the diagnosis and classification of all ASDs. Additionally, the availability of devices for transcatheter closure of secundum ASDs introduces the need for precise sizing of such defects, as well as for assessing the size of adjacent tissue rims to which the devices will be anchored. Other types of ASD require surgical closure.

Regardless of location, hemodynamically significant ASDs will be associated with evidence of RV volume overload characterized by RV enlargement and diastolic flattening of the interventricular septum. Pulmonary hypertension, which may complicate large defects, will result in flattening that persists through systole. Secundum and primum ASDs can generally be diagnosed with two-dimensional TTE. Although parasternal and apical views are useful, the subcostal view is particularly important because it optimizes the Doppler detection of shunts and minimizes the chance that normal thinning of the fossa will be mistaken for a secundum defect. TEE is typically required to detect sinus venosus and coronary sinus defects, and in an era of device closure for secundum defects, three-dimensional TEE is an essential tool for sizing defects and determining whether the surrounding tissue rims are adequate to support the closure device. With three-dimensional zoom acquisitions from the

midesophageal level at zero degrees, the TUPLE maneuver (Tilt UP and tilt Left) provides a quick method for optimizing en face displays of the septum from the RA and LA perspective (**Fig. 14-84**).⁹⁹ In the presence of an ASD, agitated saline injections may demonstrate the transient right-to-left shunts that occur in patients with dominant left-to-right shunting or evidence of negative contrast enhancement when the left-to-right shunt flow meets the contrast-enhanced RA blood pool.

The two-dimensional appearance of RV volume overload and right-sided heart enlargement is considered evidence of a hemodynamically significant shunt ($Q_p/Q_s \geq 1.5:1$). Q_p/Q_s may be calculated directly by applying the principles of the continuity equation to measure Q_p as RV SV ($\pi[D_{RVOT}/2]^2 \times VTI_{RVOT}$) and Q_s as LV SV ($\pi[D_{LVOT}/2]^2 \times VTI_{LVOT}$) (**Fig. 14-85**). Additionally, it is possible to calculate PVR in Wood units as $10(\text{Peak TR velocity}/VTI_{RVOT}) + 0.16$; normal PVR is 0.5 to 1.5 Wood units.⁸⁸

Secundum Atrial Septal Defect. Secundum ASDs account for 75% of all ASDs and 30% to 40% of congenital disease seen in patients older than 40 years (see **Chapter 62**). The two-dimensional TTE and TEE echocardiographic appearance of these defects is shown in **Figures 14-86** and **14-87**. Secundum ASDs are the only defects that are eligible for catheter-based closure. Thus echocardiographic sizing of both the defect and adjacent tissue rims is important in determining whether device closure is possible because the available devices have limitations in terms of defect size and require sufficient surrounding tissue rims for anchorage. Of the two devices currently approved by the Food and Drug Administration, the Amplatzer may be used for defects up to 35 mm if adequate tissue rims are present (see later), whereas the Helex device may be used only for defects up to 17 to 18 mm, although it may be placed successfully in patients with deficient anterior rims (see **Chapter 56**).

When sizing with two-dimensional TEE, it is important to record orthogonal diameters (see **Fig. 14-87**) and note the presence of fenestrations. Measurements should be taken in ventricular systole. Three-dimensional echocardiography, which now offers online measurement capability, greatly facilitates accurate sizing with en face displays that clearly display the defect. Three-dimensional imaging avoids the error of undersizing because of two-dimensional measurements that fail to capture the maximum diameters (**Fig. 14-88**).

The rims are defined by adjacent structures—**anterior** (toward the aorta), **posterior** (toward the pulmonary veins), **superior** (toward the SVC), and **inferior** (toward the IVC) (**Fig. 14-89**)—with three-dimensional imaging facilitating the identification of landmarks. The anterior and posterior rims may be subdivided into superior and inferior segments. If one is limited to a two-dimensional TEE approach, the zero-degree midesophageal view, complemented by the 45-degree

FIGURE 14-83 Classification of ASDs. RV = right ventricle; TV = tricuspid valve.

FIGURE 14-84 The TUPLE maneuver provides an easy method to image the right and left sides of the interatrial septum. The initial image is a zoomed three-dimensional volume set acquired from a midesophageal zero-degree window. ASD = atrial septal defect. (From Saric M, Perk G, Purgess JR, Kronzon I: Imaging atrial septal defects by real-time three-dimensional transesophageal echocardiography: Step-by-step approach. *J. Am Soc Echocardiogr* 23:1128, 2010.)

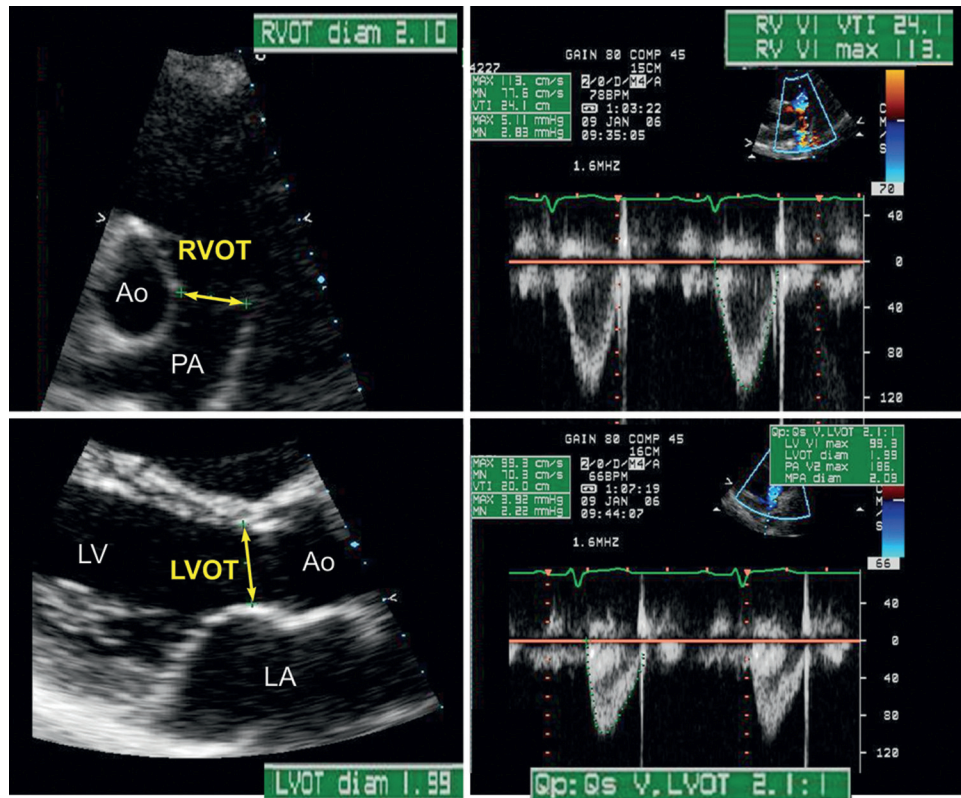

FIGURE 14-85 Q_p/Q_s calculation. For ASDs, Q_p is equivalent to RV SV, which can be determined from the CSA of the RVOT and the RVOT velocity time interval: $CSA_{RVOT} \times VTI_{RVOT}$, where $CSA_{RVOT} = \pi(D/2)^2$. Q_s is equivalent to LV SV calculated as $CSA_{LVOT} \times VTI_{LVOT}$, where $CSA_{LVOT} = \pi(D/2)^2$. The **upper** and **lower panels** illustrate the derivation of RV and LV SV, respectively. Ao = aorta; LA = left atrium; PA = pulmonary artery.

FIGURE 14-86 Parasternal (**left** and **middle panels**) and subcostal (**right panel**) images of a secundum ASD and its associated left-to-right shunt (**arrows**).

view, can be used to measure the anterior and posterior rims, whereas the 90-degree view images the superior and inferior rims.¹⁰⁰ Acceptable rim margins are 3 to 5 mm for the anterior rim and 5 to 7 mm for all other rims. Deficiency of the anterior rim (**Fig. 14-90**) is the most common, followed in frequency by deficiencies of the inferior, superior, and posterior rims.¹⁰¹

Device closure may be guided by intracardiac echocardiography or TEE, with key steps being placement of the guidewire across the defect (while avoiding the smaller secondary openings that may be present in fenestrated defects), confirmation of defect size, device placement followed by a tug to ensure optimal seating, assessment for residual shunt, and identification of complications such as pericardial effusion. Confirmation of device sizing typically includes balloon

inflation and demonstration that the size selected will eliminate shunt flow (thereby establishing the stop-flow diameter). Small residual shunts are often present immediately following deployment but will be eliminated with endothelialization of the device. The three- and two-dimensional TEE appearance of a successfully deployed Amp-latzter device is illustrated in **Figure 14-91**.

A patent foramen ovale (PFO) is a related condition characterized by incomplete fusion of the septum primum and septum secundum following birth. It may be detected by saline contrast demonstration of a right-to-left interatrial shunt, typically with maneuvers that raise RA pressure (cough, Valsalva or Müller maneuver). It is a very frequent condition that occurs in 20% to 35% of the normal population. It is a common association with aneurysm of the interatrial septum.

FIGURE 14-87 Biplane two-dimensional TEE measurement of ASD dimensions.

FIGURE 14-88 The two-dimensional TEE-measured diameter of an ASD (red line) is typically smaller than that measured by three-dimensional TEE (white dotted line).

FIGURE 14-92 Apical four-chamber views showing complete (**left panel**) and partial (**right panel**) atrioventricular canal defects. In the **left panel**, arrows outline a large defect with atrial and ventricular components. In the **right panel** there is a primum ASD (arrow) with an intact ventricular septum. LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

Echocardiography with saline contrast injection is often called on to elucidate whether a PFO is present and could allow a paradoxical embolism to occur in patients without a clear source of left-sided embolic events. Evaluation for a PFO is one reason for performing TTE and TEE in patients with transient ischemic attacks, stroke, or other embolic events.

Primum Atrial Septal Defect. Primum ASDs account for 15% to 20% of ASDs and occur as part of the spectrum of atrioventricular canal defects. They may occur as isolated defects (partial atrioventricular canal defect) or be accompanied by inlet VSDs (complete atrioventricular canal defect). Partial canal defects typically have an associated cleft mitral valve. In complete canal defects there is a common single atrioventricular valve. Atrioventricular canal defects are the most common congenital heart abnormality in Down syndrome.

Primum defects can be seen on apical or subcostal views if posterior angulation is ensured to demonstrate the inlet portion of the ventricular septum (**Fig. 14-92**). Primum defects must be closed surgically.

Sinus Venosus Atrial Septal Defect. Sinus venosus ASDs account for 2% to 10% of ASDs and occur in two locations. The SVC type creates a confluence between the left atrium, right atrium, and SVC as it enters the right atrium. It is frequently accompanied by partial anomalous drainage of the right upper pulmonary vein, which is created when this vein enters the confluence. Partial anomalous drainage contributes to the left-to-right shunt. IVC-type defects are less common and create a confluence between the left atrium, right atrium, and IVC as it enters the right atrium. They may be accompanied by partial anomalous drainage of the right lower pulmonary vein. These defects should be suspected in patients with markers of RV volume overload without apparent cause. Typically, TEE is required to make the diagnosis, although SVC-type defects may be demonstrated with subcostal TTE. **Figure 14-93** shows the TEE appearance of a

sinus venosus ASD with partial anomalous pulmonary venous drainage. Sinus venosus ASDs must be closed surgically.

Coronary Sinus Atrial Septal Defect. Coronary sinus ASDs are rare and may be associated with fenestrations or complete unroofing of the coronary sinus into the left atrium. They are frequently associated with a persistent left SVC, a more frequent finding (found in 0.3% of the general population) and the most common cause of a dilated coronary sinus in general. The diagnosis is facilitated with TEE.

Ventricular Septal Defect

There are a number of classifications for VSDs. One anatomic classification is demonstrated in **Figure 14-94**, and **Figure 14-95** outlines the division of the interventricular septum into its membranous, inlet, outlet, and trabecular portions along with the echocardiographic views that may be used to identify defects in each of these locations. VSDs vary in size and are considered to be small (restrictive) when less than half the size of the aortic root and when the LV-RV pressure gradient is greater than 64 mm Hg. Moderately restrictive VSDs are approximately half the size of the root with gradients of approximately 36 mm Hg. With larger nonrestrictive defects, LV and RV systolic pressures are equalized. It is these latter defects that most commonly result in irreversible pulmonary vascular changes (Eisenmenger syndrome). Echocardiography may be used to size defects and LV-RV gradients. Shunting may be assessed by both color flow mapping and Q_p/Q_s calculated with the continuity equation. Although chamber size may be normal in the setting of small defects, LV and LA enlargement is expected in those that are hemodynamically significant.

FIGURE 14-93 Transesophageal images of a sinus venosus ASD (SVC type) with anomalous drainage of the right upper pulmonary vein (RUPV). A confluence is created between the SVC, RUPV, and adjoining atria. LA = left atrium; RA = right atrium.

FIGURE 14-94 Anatomic classification system for VSDs.

Membranous (Paramembranous) and Outlet Ventricular Septal Defects

Eighty percent of VSDs involve the membranous septum. They vary in size, but even small defects can generally be detected on the parasternal long-axis view on the basis of a high-velocity jet. Membranous defects may be associated with wind-sock aneurysms that reflect varying degrees of spontaneous closure (**Fig. 14-96**). Even though the jets of membranous and outlet defects appear similar on the parasternal long-axis view, these defects may be distinguished from one another on short-axis views at the level of the great vessels. Membranous defects will be directed toward the septal leaflet of the tricuspid valve (10 to 11 o'clock position on the short-axis clock face), whereas outlet defects will be associated with jets that are directed toward the pulmonic valve (**Fig. 14-97**). Either defect may be accompanied by aortic cusp prolapse and consequent aortic regurgitation.

Inlet Ventricular Septal Defects

Inlet defects have been addressed in the preceding discussion of complete atrioventricular canal defects. Although they are often easily detected as in **Figure 14-92** (left panel), they may be partially closed by adjacent atrioventricular valve tissue. In such situations, nonstandard views and TEE may be required to detect the ventricular component of the canal defect.

Muscular Ventricular Septal Defects

Muscular defects vary considerably in size and location and may be multiple. When small and serpiginous they may easily be missed with

conventional echocardiographic views. Because these small defects are associated with loud murmurs with or without a thrill, a detailed evaluation using non-standard views is warranted in any patient with these clinical manifestations (**Fig. 14-98**).

Transposition of the Great Arteries

Transposition of the great arteries (TGA) arises from failure of the aortico-pulmonary septum to take its normal spiraling course (**see Chapter 62**). In D-TGA, the aorta lies anterior and to the right of the pulmonary artery and arises from the right ventricle with the pulmonary artery arising from the left ventricle (**Fig. e14-13, middle panel**). D-TGA accounts for 5% to 7% of all congenital heart disease and, in the absence of

shunting (VSD, ASD, patent ductus arteriosus) or surgery, D-TGA will be fatal. The most common associated anomalies are VSD (30% to 45%), pulmonary outflow tract obstruction (25%), and coarctation. Patients seen by cardiologists treating adults with congenital heart disease will have undergone corrective surgery consisting of either an atrial baffle/switch (Mustard or Senning) procedure or, more recently, an arterial switch procedure.¹⁰²

With baffle procedures, the systemic venous baffle directs deoxygenated blood across the mitral valve into the left ventricle, from which it is ejected into the pulmonary artery. The pulmonary venous baffle directs oxygenated blood returning from the lungs to the tricuspid valve and into the right ventricle, from which it is pumped into the aorta. The end result is a “physiologic” circulation. Although short- and mid-term results are good, the right ventricle ultimately fails because of its inability to sustain its role as the systemic ventricle. Other complications detectable by echocardiography include baffle obstruction, baffle leaks, and pulmonary hypertension (the cause of which is incompletely understood).

The echocardiographic hallmark of transposition is parallel orientation of the great vessels, best appreciated on parasternal long-axis or apical views (**Fig. 14-99**). The diagnosis can be confirmed by demonstrating that the posterior great vessel (the pulmonary artery) bifurcates and the anterior aorta gives off arch vessels. In patients with D-TGA who have undergone atrial switch surgery, the baffles can be traced as they crisscross the atrium, with color flow mapping and spectral Doppler identifying areas of obstruction and baffle leak. The hypertrophied right ventricle has the rounded contour typically associated with the left ventricle, whereas the left ventricle is crescentic, a result of reversal of the normal septal curvature because of systemic RV pressures (**see Fig. 14-99**). RV systolic function may be reduced with accompanying functional TR.

L-TGA, also termed congenitally corrected transposition, is rare and accounts for less than 1% of all congenital heart disease. In this condition, transposition of the great vessels, with the aorta anterior and typically to the left of the pulmonary artery, is also accompanied by ventricular inversion. Thus systemic venous blood returning to the right atrium drains into the morphologic left ventricle and is pumped into the pulmonary artery. Pulmonary venous blood returning to the left atrium crosses the tricuspid valve into the morphologic right ventricle, from which it is ejected into the aorta. Thus the circulation is “normalized” (**see Fig. e14-13, right panel**). Associated abnormalities are common and include VSD (70% of patients), pulmonary outflow tract obstruction, typically subvalvular (40%), and abnormalities of the tricuspid (systemic atrioventricular) valve (90%). Patients, particularly those without associated anomalies, may remain undiagnosed until adulthood, but eventually the morphologic right ventricle will fail because it cannot meet the pressure demands of the systemic circulation.

FIGURE e14-13 Schematic representation of blood flow through hearts with D-TGA and L-TGA.

FIGURE 14-95 Echocardiographic views used in imaging the interventricular septum. A3C = apical three-chamber view; Ao = aorta; AVL = aortic valve level; LA = left atrium; LV = left ventricle; MVL = mitral valve leaflet; PLAX = parasternal long-axis view; PML = posterior mitral leaflet; RA = right atrium; RV = right ventricle. (Modified from Bulwer BE, Rivero JM [eds]: *Echocardiography Pocket Guide: The Transthoracic Examination*. Burlington, Mass, Jones & Bartlett Learning, 2011, 2013, p 142. Reprinted with permission.)

FIGURE 14-96 Parasternal views of a membranous VSD partially closed with a wind-sock aneurysm. **Left**, A systolic left-to-right jet is identified. **Middle**, With slight angulation, a wind-sock aneurysm representing partial spontaneous closure of the defect is identified. **Right**, In the short-axis view, the wind sock helps localize the VSD to the 11 o'clock position, as opposed to outlet defects, which are seen in the 12 to 2 o'clock position (see Fig. 14-97).

FIGURE 14-97 Parasternal images illustrating an outlet VSD. In the parasternal long-axis view (**left** and **middle panels**), the VSD jet and the defect (arrow) may be indistinguishable from those of a membranous defect. However, in the short axis (**right panel**), the jet is seen at the 12 o'clock position immediately next to the pulmonic valve (arrow).

FIGURE 14-98 Parasternal short-axis (**left panel**) and off-axis apical (**right panel**) views demonstrating a serpiginous muscular VSD. The *white arrows* point to LV and RV entry points. The *red arrow* identifies a small left-to-right shunt.

FIGURE 14-99 D-Transposition of the great vessels after Mustard baffle surgery. **Top left**, Parasternal long-axis view showing parallel orientation of the aorta (Ao) and pulmonary artery (PA). The aorta is anterior. **Top middle**, Parasternal short-axis view showing septal inversion reflecting the fact that the right ventricle (RV) is the systemic ventricle. **Top right**, Apical four-chamber view showing the pulmonary venous baffle (PVB), which directs pulmonary venous flow across the tricuspid valve into the RV. **Bottom left**, The four-chamber view has been angulated to demonstrate the systemic venous baffle (SVB), which directs systemic venous return across the mitral valve into the left ventricle (LV). Note the right ventricular hypertrophy and enlargement. **Bottom right**, The four-chamber view is angulated anteriorly to demonstrate the connection between the LV and PA. Arrows point to the PA bifurcation.

Echocardiographic features again include parallel orientation of the great vessels as is seen with all cases of transposition, but on apical views ventricular inversion becomes apparent. Ventricular morphology may be determined by the structure of its atrioventricular valve and the pattern of trabeculation. The morphologic right ventricle is associated with a tricuspid atrioventricular valve, which is identified by the presence of three leaflets and leaflet insertion that is apical to that of the mitral valve. The morphologic right ventricle

is coarsely trabeculated with a moderator band, whereas the morphologic left ventricle is smooth walled and has two discrete papillary muscles. In assessing ventricular morphology via the four-chamber view, it is essential to maintain standard transducer orientation and avoid rotating the transducer so that an image is created in which the right and left ventricles occupy their expected positions. **Figure 14-100** illustrates ventricular inversion in a patient with L-TGA. As with D-TGA, the morphologic right ventricle

FIGURE 14-100 Apical four-chamber view in a patient with L-TGA. The ventricles are inverted with the right ventricle (RV) to the right identified on the basis of its heavy trabeculation and tricuspid atrioventricular valve (*thin arrow*). Although the insertion of the tricuspid valve is always apical to that of the mitral valve, in this case the offset is accentuated consistent with the Ebstein anomaly. Unlike isolated Ebstein anomaly, that seen with L-TGA does not have a sail-like leaflet or adherence of the septal leaflet to the septum. The *heavy arrow* points to the mitral valve. LA = left atrium; LV = left ventricle; RA = right atrium.

is hypertrophied with a round contour and the morphologic left ventricle is crescentic. The septal curvature is reversed, consistent with the systemic pressure in the morphologic right ventricle.

Tetralogy of Fallot. This is the most common form of cyanotic congenital heart disease and accounts for 10% of all congenital heart cases. The tetralogy of abnormalities consists of an overriding aorta, nonrestrictive subaortic VSD, RVOT obstruction (typically infundibular with variable valvular abnormalities), and secondary RV hypertrophy. Each of these features is readily identifiable with echocardiography as shown in **Figure 14-101**. Pentalogy of Fallot refers to the situation in which an ASD is also present.

Surgery for the tetralogy consists of patching the VSD and a tailored approach to relieving the RVOT obstruction. Pulmonic regurgitation, sometimes severe, is a frequent finding after surgery for the tetralogy and may drive the need for repeated surgery. Other problems to remain vigilant for include residual infundibular (subvalvular) and supravalvular pulmonic stenosis, as well as aneurysmal degeneration of the patch used to open up the infundibulum and/or pulmonary artery.

CARDIAC PROCEDURES AND FUTURE DIRECTIONS

The role of TTE and TEE has been discussed in conventional surgical procedures, particularly in the setting of evaluation and treatment of CAD, cardiomyopathies, valvular disease, LVADs, and intracardiac shunts and congenital heart disease. The past decade has seen swift and remarkable advances in percutaneous interventions, which often require accurate preprocedure assessment and skilled intraprocedure

echocardiography to guide effective deployment of devices. Knowledge of how these newer and developing devices work and their potential failings is essential for complete follow-up echocardiographic evaluation.

Percutaneous valvuloplasty for aortic stenosis and MR has now entered the commercial realm (see **Chapter 56**) and is currently an attractive alternative for patients at high surgical risk. Transcatheter pulmonary valve implantation is now routine in pediatric centers experienced in congenital heart disease. In general, echocardiographic guidance is required for proper device selection (with regard to type and size), placement, and deployment of most of the available percutaneous devices. Transcatheter aortic valve implantation can be performed via transfemoral or LV apical (and other alternative) approaches. TEE is highly useful to ensure proper seating of the device across the aortic annulus and assess for adequate expansion to seal off the periaortic areas and preclude paravalvular leakage. Care must be taken to avoid occlusion of the coronary artery ostia; candidates should ideally have coronary ostia that are 1.0 cm or greater from the aortic annulus, and surveillance for wall motion abnormalities should continue during and after balloon inflations. Paravalvular aortic insufficiency is not uncommon; if the degree is

FIGURE 14-101 Transesophageal images of a patient with tetralogy of Fallot. **Upper left**, Midesophageal image showing the aorta (Ao) overriding a large (nonrestrictive) VSD (*arrow*). **Upper right**, There is mild aortic regurgitation. **Lower left**, From a deep transgastric view, severe right ventricular hypertrophy is seen. The *arrow* points to the VSD. **Lower right**, In this midesophageal view, focal infundibular narrowing is seen (*arrow*). The pulmonic valve (PV) is not well seen but, in other views, was shown to be normal. LV = left ventricle; RV = right ventricle.

significant, regurgitation may be ameliorated by further reexpansion of the stented valve or even by implantation of a second valve.

Transcatheter mitral valvuloplasty devices for MR, which are commercially available in Europe, are ideally implanted under TEE guidance, although use of TTE alone is feasible. Device implantation is highly dependent on echocardiography to properly position the delivery catheter and the device in the left atrium. Echocardiography is used to grade the degree of reduction in MR and guide the amount of device repositioning if necessary.

The increasing population with structural and adult congenital heart disease has led to demand for continued innovation in structural interventions. Current interventions include stenting of the pulmonary arteries or veins, percutaneous treatment of complex lesions (coronary fistulas, other vascular malformations, and collaterals), angioplasty and stenting of surgical conduits and aortic coarctation, and a growing list of other minimally invasive interventions for conditions that were previously remediable only by open surgery. In many cases, adjunctive modalities such as intracardiac echocardiography, CT, and CMR are complementary tools.

In the subspecialty of electrophysiology, occlusion of the LA appendage is possible with a variety of devices and is targeted toward patients at high risk for recurrent strokes (despite anticoagulation or unable to take anticoagulants). Echocardiography will continue to be vital for patient selection, device deployment, and assessment of the effectiveness and complications as these and other interventions move through experimental trials and ultimately filter into the clinical arena.

Handheld Echocardiography

The era of miniaturization has ushered in increasingly smaller and capable portable ultrasound machines, which were introduced commercially in 2004. Current laptop-size devices are a lightweight alternative to the 400-lb traditional full-size machines and have increased the availability and usefulness of cardiac ultrasound at the point of care. Laptop ultrasound has virtually all the capabilities of full-size traditional machines, including the capability for tissue Doppler and strain imaging, stress and TEE studies, automatic quantification of LVEF, and more recently, four-dimensional imaging. They can operate wirelessly. Many systems offer the capability to also perform vascular, abdominal, and obstetric ultrasound on the same machine and are capable of accommodating a wide range of transducers, including those used in pediatrics.

Handheld ultrasound devices have been introduced in the last 5 years and are small enough to fit in the physician's coat pocket. They may be used as an extension to the physical examination and are more likely to be readily available in an acute emergency for a focused examination. In the hands of experienced sonographers, the current devices offer harmonic two-dimensional and color Doppler imaging with good image quality and accuracy when compared with conventional machines.¹⁰³ However, education and training are undoubtedly required for optimal use by noncardiologists. The current handheld devices do not support spectral Doppler and hence are limited in the quantification of valve stenosis. However, it is likely that with enough user experience and continual improvements in design and function, these instruments will become as familiar in clinical settings as the stethoscope. The lower cost and portability also render the technology more accessible for health care in underdeveloped regions.

APPROPRIATE USE CRITERIA

Echocardiography

Scott D. Solomon and Robert O. Bonow

During the past three decades there has been explosive growth in the use of cardiac imaging, particularly in the applications of echocardiography, Doppler echocardiography, and stress echocardiography.¹ The American College of Cardiology/American Heart Association (ACC/AHA) guidelines for the use of echocardiography were last updated in 2003.² Whether cardiac imaging and in particular echocardiography leads to enhanced quality of care and improved patient outcomes is unclear. It is difficult to tie an imaging test to patient outcomes because any impact of diagnostic testing on patient-related outcomes is ultimately tied to downstream management strategies that the diagnostic tests may or may not set in motion. In addition, no prospective randomized trials have been designed to demonstrate the efficacy of imaging in achieving optimal patient outcomes. Thus no firm foundation on which to develop evidence-based guidelines is available.

Against this background, the ACC has moved from the development of practice guidelines in cardiovascular imaging to the development of appropriate use criteria (AUC).^{3,4} Partnering with a number of subspecialty societies, the ACC has spearheaded the delivery of AUC for imaging, which are designed to define the appropriate test for the appropriate indication in the appropriate patient. The first such criteria were developed for single proton emission computed tomography (SPECT) myocardial perfusion imaging, followed shortly

thereafter with AUC for cardiac magnetic resonance (CMR), cardiac computed tomography (CT), echocardiography, and stress echocardiography. In subsequent chapters the AUC are described for nuclear cardiology (see Chapter 16), CMR (see Chapter 17), and cardiac CT (see Chapter 18). The process used for development of appropriateness criteria is only partially evidence based and is heavily weighted by expert consensus.

The AUC for echocardiography are based on a number of common clinical scenarios in which imaging is often used. These scenarios are then rated by a panel with a broad array of expertise (i.e., not just imaging experts) to evaluate the “appropriateness” of echocardiography in each situation in terms of the following definition: “An appropriate imaging study is one in which the expected incremental information, combined with clinical judgment, exceeds the expected negative consequences by a sufficiently wide margin for a specific indication that the procedure is generally considered acceptable care and a reasonable approach for the indication.”⁵ Rating scores are made on a scale of 1 to 9, in which a score of 9 indicates highly appropriate use of testing. Using an iterative modified Delphi exercise process with predefined rules, a final rating score is established for each indication and grouped as A, score of 7 to 9, indicating an appropriate test for the specific indication (the test is generally acceptable and is a reasonable approach for the indication); U, score of 4 to 6, indicating uncertainty for the specific indication (the test may be generally acceptable and may be a reasonable approach for the indication); and I, score of 1 to 3, indicating an inappropriate test for that indication (the test is not generally acceptable and is not a reasonable approach for the indication).⁵

The AUC for echocardiography were first published in 2007,⁶ followed by AUC for stress echocardiography in 2008.⁷ The echocardiography AUC were updated in 2011.⁸ These criteria are summarized in Table 14G-1. The current AUC methodology⁹ has changed the

TABLE 14G-1 Echocardiography Appropriate Use: Transthoracic, Transesophageal, and Stress

TRANSESOPHAGEAL ECHOCARDIOGRAPHY FOR GENERAL EVALUATION OF CARDIAC STRUCTURE AND FUNCTION		Appropriateness Score (1-9)
Indication		
Suspected Cardiac Cause—General		
1.	Symptoms or conditions potentially related to a suspected cardiac cause, including but not limited to chest pain, shortness of breath, TIA, stroke, or peripheral embolic event	A (9)
2.	Previous testing that is concerning for heart disease or structural abnormality, including but not limited to chest radiography, baseline scout images for stress echocardiography, electrocardiography, or cardiac biomarkers	A (9)
Arrhythmias		
3.	Infrequent APCs or VPCs or palpitations without other evidence of heart disease	I (2)
4.	Frequent VPCs or exercise-induced VPCs	A (8)
5.	Sustained or nonsustained atrial fibrillation, SVT, or VT	A (9)
6.	Asymptomatic isolated sinus bradycardia	I (2)
Lightheadedness/Presyncope/Syncope		
7.	Clinical symptoms or signs consistent with a cardiac diagnosis known to cause lightheadedness/presyncope/syncope (including but not limited to aortic stenosis, hypertrophic cardiomyopathy, or heart failure)	A (9)
8.	Lightheadedness/presyncope/syncope when there is very low clinical suspicion for cardiovascular disease	I (3)
9.	Syncope when no other symptoms or signs of cardiovascular disease are present	A (7)
Evaluation of Ventricular Function		
10.	Initial evaluation of ventricular function (e.g., screening) with no symptoms or signs of cardiovascular disease	I (2)
11.	Routine reevaluation of ventricular function with known CAD and no change in clinical status or findings on cardiac examination	I (3)
12.	Evaluation of left ventricular function with previous ventricular function evaluation showing normal function (such as previous echocardiography, left ventriculography, CT, SPECT, CMR) in patients in whom there has been no change in clinical status or findings on cardiac examination	I (1)

TABLE 14G-1 Echocardiography Appropriate Use: Transthoracic, Transesophageal, and Stress—cont'd

TRANSESOPHAGEAL ECHOCARDIOGRAPHY FOR GENERAL EVALUATION OF CARDIAC STRUCTURE AND FUNCTION		
	Indication	Appropriateness Score (1-9)
Perioperative Evaluation		
13.	Routine perioperative evaluation of ventricular function with no symptoms or signs of cardiovascular disease	I (2)
14.	Routine perioperative evaluation of cardiac structure and function before noncardiac solid organ transplantation	U (6)
Pulmonary Hypertension		
15.	Evaluation of suspected pulmonary hypertension, including evaluation of right ventricular function and estimated pulmonary artery pressure	A (9)
16.	Routine (<1 year) reevaluation of known pulmonary hypertension without change in clinical status or findings on cardiac examination	I (3)
17.	Routine (≥1 year) reevaluation of known pulmonary hypertension without change in clinical status or findings on cardiac examination	A (7)
18.	Reevaluation of known pulmonary hypertension if change in clinical status or findings on cardiac examination occurs or to guide therapy	A (9)
TRANSTHORACIC ECHOCARDIOGRAPHY FOR CARDIOVASCULAR EVALUATION IN AN ACUTE SETTING		
Hypotension or Hemodynamic Instability		
19.	Hypotension or hemodynamic instability of uncertain or suspected cardiac cause	A (9)
20.	Assessment/monitoring of volume status in a critically ill patient	U (5)
Myocardial Ischemia/Infarction		
21.	Acute chest pain with suspected myocardial infarction and nondiagnostic ECG when a resting echocardiogram can be performed during pain	A (9)
22.	Evaluation of a patient without chest pain but with other features of an ischemic equivalent or laboratory markers indicative of ongoing myocardial infarction	A (8)
23.	Suspected complication of myocardial ischemia/infarction, including but not limited to acute mitral regurgitation, ventricular septal defect, free wall rupture/tamponade, shock, right ventricular involvement, heart failure, or thrombus	A (9)
Evaluation of Ventricular Function after Acute Coronary Syndrome		
24.	Initial evaluation of ventricular function following ACS	A (9)
25.	Reevaluation of ventricular function following ACS during recovery phase when results will guide therapy	A (9)
Respiratory Failure		
26.	Respiratory failure or hypoxemia of uncertain cause	A (8)
27.	Respiratory failure or hypoxemia when a noncardiac cause of respiratory failure has been established	U (5)
Pulmonary Embolism		
28.	Suspected pulmonary embolism to establish the diagnosis	I (2)
29.	Known acute pulmonary embolism to guide therapy (e.g., thrombectomy and thrombolytics)	A (8)
30.	Routine reevaluation of previous pulmonary embolism with normal right ventricular function and pulmonary artery systolic pressure	I (1)
31.	Reevaluation of known pulmonary embolism after thrombolysis or thrombectomy for assessment of change in right ventricular function and/or pulmonary artery pressure	A (7)
Cardiac Trauma		
32.	Severe deceleration injury or chest trauma when valve injury, pericardial effusion, or cardiac injury is possible or suspected	A (9)
33.	Routine evaluation in the setting of mild chest trauma with no changes on the ECG or biomarker elevation	I (2)
TRANSTHORACIC ECHOCARDIOGRAPHY FOR EVALUATION OF VALVULAR FUNCTION		
Murmur or Click		
34.	Initial evaluation when there is a reasonable suspicion of valvular or structural heart disease	A (9)
35.	Initial evaluation when there is very low suspicion of valvular or structural heart disease	I (2)
36.	Reevaluation in a patient without valvular disease on a previous echocardiogram and no change in clinical status or findings on cardiac examination	I (1)
37.	Reevaluation of known valvular heart disease with a change in clinical status or findings on cardiac examination or to guide therapy	A (9)

Continued

**TABLE 14G-1 Echocardiography Appropriate Use: Transthoracic, Transesophageal, and Stress—cont'd**

TRANSTHORACIC ECHOCARDIOGRAPHY FOR EVALUATION OF VALVULAR FUNCTION			Appropriateness Score (1-9)
Indication			
Native Valvular Stenosis			
38.	Routine (<3 years) reevaluation of mild valvular stenosis without change in clinical status or findings on cardiac examination		I (3)
39.	Routine (≥3 years) reevaluation of mild valvular stenosis without change in clinical status or findings on cardiac examination		A (7)
40.	Routine (<1 year) reevaluation of moderate or severe valvular stenosis without change in clinical status or findings on cardiac examination		I (3)
41.	Routine (≥1 year) reevaluation of moderate or severe valvular stenosis without change in clinical status or findings on cardiac examination		A (8)
Native Valvular Regurgitation			
42.	Routine reevaluation of trace valvular regurgitation		I (1)
43.	Routine (<3 years) reevaluation of mild valvular regurgitation without change in clinical status or findings on cardiac examination		I (1)
44.	Routine (≥3 years) reevaluation of mild valvular regurgitation without change in clinical status or findings on cardiac examination		U (4)
45.	Routine (<1 year) reevaluation of moderate or severe valvular regurgitation without change in clinical status or findings on cardiac examination		U (6)
46.	Routine (≥1 year) reevaluation of moderate or severe valvular regurgitation without change in clinical status or findings on cardiac examination		A (8)
Prosthetic Valve			
47.	Initial postoperative evaluation of prosthetic valve for establishment of baseline		A (9)
48.	Routine (<3 years) reevaluation of prosthetic valve if no known or suspected valve dysfunction		I (3)
49.	Routine (≥3 years) reevaluation of prosthetic valve if no known or suspected valve dysfunction		A (7)
50.	Evaluation of prosthetic valve with suspected dysfunction or change in clinical status or findings on cardiac examination		A (9)
51.	Reevaluation of known prosthetic valve dysfunction when it would change management or guide therapy		A (9)
Infective Endocarditis (Native or Prosthetic Valves)			
52.	Initial evaluation of suspected infective endocarditis with positive blood cultures or a new murmur		A (9)
53.	Transient fever without evidence of bacteremia or a new murmur		I (2)
54.	Transient bacteremia with a pathogen not typically associated with infective endocarditis and/or documented nonendovascular source of infection		I (3)
55.	Reevaluation of infective endocarditis at high risk for progression or complication or with a change in clinical status or findings on cardiac examination		A (9)
56.	Routine reevaluation of uncomplicated infective endocarditis when no change in management is contemplated		I (2)
TRANSTHORACIC ECHOCARDIOGRAPHY FOR EVALUATION OF INTRACARDIAC AND EXTRACARDIAC STRUCTURES AND CHAMBERS			
57.	Suspected cardiac mass		A (9)
58.	Suspected cardiovascular source of embolus		A (9)
59.	Suspected pericardial conditions		A (9)
60.	Routine reevaluation of known small pericardial effusion with no change in clinical status		I (2)
61.	Reevaluation of known pericardial effusion to guide management or therapy		A (8)
62.	Guidance of percutaneous noncoronary cardiac procedures, including but not limited to pericardiocentesis, septal ablation, or right ventricular biopsy		A (9)
TRANSTHORACIC ECHOCARDIOGRAPHY FOR EVALUATION OF AORTIC DISEASE			
63.	Evaluation of the ascending aorta in the setting of a known or suspected connective tissue disease or genetic condition that predisposes to aortic aneurysm or dissection (e.g., Marfan syndrome)		A (9)
64.	Reevaluation of known ascending aortic dilation or history of aortic dissection to establish a baseline rate of expansion or when the rate of expansion is excessive		A (9)
65.	Reevaluation of known ascending aortic dilation or history of aortic dissection with a change in clinical status or findings on cardiac examination or when findings may alter management or therapy		A (9)
66.	Reevaluation of known ascending aortic dilation or history of aortic dissection without a change in clinical status or findings on cardiac examination when findings would not change management or therapy		I (3)

TABLE 14G-1 Echocardiography Appropriate Use: Transthoracic, Transesophageal, and Stress—cont'd

TRANSTHORACIC ECHOCARDIOGRAPHY FOR EVALUATION OF HYPERTENSION, HEART FAILURE, OR CARDIOMYOPATHY		
	Indication	Appropriateness Score (1-9)
Hypertension		
67.	Initial evaluation of suspected hypertensive heart disease	A (8)
68.	Routine evaluation of systemic hypertension without suspected hypertensive heart disease	I (3)
69.	Reevaluation of known hypertensive heart disease without change in clinical status or findings on cardiac examination	U (4)
Heart Failure		
70.	Initial evaluation of known or suspected heart failure (systolic or diastolic) based on symptoms, signs, or abnormal test results	A (9)
71.	Reevaluation of known heart failure (systolic or diastolic) with change in clinical status or findings on cardiac examination and no clear precipitating change in medication or diet	A (8)
72.	Reevaluation of known heart failure (systolic or diastolic) with change in clinical status or findings on cardiac examination and a clear precipitating change in medication or diet	U (4)
73.	Reevaluation of known heart failure (systolic or diastolic) to guide therapy	A (9)
74.	Routine (<1 year) reevaluation of heart failure (systolic or diastolic) when there is no change in clinical status or findings on cardiac examination	I (2)
75.	Routine (≥1 year) reevaluation of heart failure (systolic or diastolic) when there is no change in clinical status or findings on cardiac examination	U (6)
Device Evaluation (Including Pacemaker, Implantable Cardioverter-Defibrillator, or Cardiac Resynchronization Therapy)		
76.	Initial evaluation or reevaluation after revascularization and/or optimal medical therapy to determine candidacy for device therapy and/or to determine optimal choice of device	A (9)
77.	Initial evaluation for optimization of device for cardiac resynchronization therapy after implantation	U (6)
78.	Known implanted pacing device with symptoms possibly caused by device complication or suboptimal pacing device settings	A (8)
79.	Routine (<1 year) reevaluation of implanted device without change in clinical status or findings on cardiac examination	I (1)
80.	Routine (≥1 year) reevaluation of implanted device without change in clinical status or findings on cardiac examination	I (3)
Ventricular Assist Devices and Cardiac Transplantation		
81.	To determine candidacy for ventricular assist device	A (9)
82.	Optimization of ventricular assist device settings	A (7)
83.	Reevaluation of signs/symptoms suggestive of ventricular assist device–related complications	A (9)
84.	Monitoring for rejection in a cardiac transplant recipient	A (7)
85.	Cardiac structure and function evaluation in a potential heart donor	A (9)
Cardiomyopathies		
86.	Initial evaluation of known or suspected cardiomyopathy (e.g., restrictive, infiltrative, dilated, hypertrophic, or genetic cardiomyopathy)	A (9)
87.	Reevaluation of known cardiomyopathy with change in clinical status or findings on cardiac examination or to guide therapy	A (9)
88.	Routine (<1 year) reevaluation of known cardiomyopathy without change in clinical status or findings on cardiac examination	I (2)
89.	Routine (≥1 year) reevaluation of known cardiomyopathy without change in clinical status or findings on cardiac examination	U (5)
90.	Screening evaluation for structure and function in first-degree relatives of a patient with inherited cardiomyopathy	A (9)
91.	Baseline and serial reevaluations in patients undergoing therapy with cardiotoxic agents	A (9)
TRANSTHORACIC ECHOCARDIOGRAPHY FOR ADULT CONGENITAL HEART DISEASE		
92.	Initial evaluation of known or suspected adult congenital heart disease	A (9)
93.	Known adult congenital heart disease with change in clinical status or findings on cardiac examination	A (9)
94.	Reevaluation to guide therapy for known adult congenital heart disease	A (9)
95.	Routine (<2 years) reevaluation of adult congenital heart disease following complete repair: Without residual structural or hemodynamic abnormality Without change in clinical status or findings on cardiac examination	I (3)

Continued

**TABLE 14G-1 Echocardiography Appropriate Use: Transthoracic, Transesophageal, and Stress—cont'd**

TRANSTHORACIC ECHOCARDIOGRAPHY FOR ADULT CONGENITAL HEART DISEASE		
	Indication	Appropriateness Score (1-9)
96.	Routine (≥ 2 years) reevaluation of adult congenital heart disease following complete repair: Without residual structural or hemodynamic abnormality Without change in clinical status or findings on cardiac examination	U (6)
97.	Routine (< 1 year) reevaluation of congenital heart disease following incomplete or palliative repair: With residual structural or hemodynamic abnormality Without change in clinical status or findings on cardiac examination	U (5)
98.	Routine (≥ 1 year) reevaluation of congenital heart disease following incomplete or palliative repair: With residual structural or hemodynamic abnormality Without change in clinical status findings on cardiac examination	A (8)
TRANSESOPHAGEAL ECHOCARDIOGRAPHY		
TEE as Initial or Supplemental Test—General Uses		
99.	Use of TEE when there is a high likelihood of a nondiagnostic TTE because of patient characteristics or inadequate visualization of relevant structures	A (8)
100.	Routine use of TEE when a diagnostic TTE is reasonably anticipated to resolve all diagnostic and management concerns	I (1)
101.	Reevaluation of previous TEE findings for interval change (e.g., resolution of thrombus after anticoagulation, resolution of vegetation after antibiotic therapy) when a change in therapy is anticipated	A (8)
102.	Reevaluation of previous TEE findings for interval change (e.g., resolution of thrombus after anticoagulation, resolution of vegetation after antibiotic therapy) when no change in therapy is anticipated	I (2)
103.	Guidance during percutaneous noncoronary cardiac interventions, including but not limited to closure device placement, radiofrequency ablation, and percutaneous valve procedures	A (9)
104.	Suspected acute aortic pathology, including but not limited to dissection/transection	A (9)
105.	Routine assessment of pulmonary veins in asymptomatic patient after pulmonary vein isolation	I (3)
TEE as Initial or Supplemental Test—Valvular Disease		
106.	Evaluation of valvular structure and function to assess suitability for and assist in planning of an intervention	A (9)
107.	To diagnose/manage infective endocarditis with a low pretest probability (e.g., transient fever, known alternative source of infection, or negative blood cultures/atypical pathogen for endocarditis)	I (3)
108.	To diagnose/manage infective endocarditis with a moderate or high pretest probability (e.g., staphylococcal bacteremia, fungemia, prosthetic heart valve, or intracardiac device)	A (9)
TEE as Initial or Supplemental Test—Embolic Event		
109.	Evaluation for cardiovascular source of embolus with no identified noncardiac source	A (7)
110.	Evaluation for cardiovascular source of embolus with a previously identified noncardiac source	U (5)
111.	Evaluation for cardiovascular source of embolus with a known cardiac source in which TEE would not change management	I (1)
TEE as Initial Test—Atrial Fibrillation/Flutter		
112.	Evaluation to facilitate clinical decision making with regard to anticoagulation, cardioversion, and/or radiofrequency ablation	A (9)
113.	Evaluation when a decision has been made to anticoagulate and not to perform cardioversion	I (2)
STRESS ECHOCARDIOGRAPHY FOR DETECTION OF CORONARY ARTERY/RISK ASSESSMENT: SYMPTOMATIC OR ISCHEMIC EQUIVALENT		
Evaluation of Ischemic Equivalent (Nonacute)		
114.	Low pretest probability of CAD ECG interpretable <i>and</i> able to exercise	I (3)
115.	Low pretest probability of CAD ECG uninterpretable <i>or</i> unable to exercise	A (7)
116.	Intermediate pretest probability of CAD ECG interpretable <i>and</i> able to exercise	A (7)
117.	Intermediate pretest probability of CAD ECG uninterpretable <i>or</i> unable to exercise	A (9)
118.	High pretest probability of CAD Regardless of ECG interpretability and ability to exercise	A (7)

TABLE 14G-1 Echocardiography Appropriate Use: Transthoracic, Transesophageal, and Stress—cont'd

STRESS ECHOCARDIOGRAPHY FOR DETECTION OF CORONARY ARTERY/RISK ASSESSMENT: SYMPTOMATIC OR ISCHEMIC EQUIVALENT			Appropriateness Score (1-9)
Indication			
Acute Chest Pain			
119.	Possible ACS ECG: no ischemic changes or uninterpretable ECG Low-risk TIMI score Negative troponin levels		A (7)
120.	Possible ACS ECG: no ischemic changes or uninterpretable ECG Low-risk TIMI score Peak troponin: borderline, equivocal, minimally elevated		A (7)
121.	Possible ACS ECG: no ischemic changes or uninterpretable ECG High-risk TIMI score Negative troponin levels		A (7)
122.	Possible ACS ECG: no ischemic changes or uninterpretable ECG High-risk TIMI score Peak troponin: borderline, equivocal, minimally elevated		A (7)
123.	Definite ACS		I (1)
STRESS ECHOCARDIOGRAPHY FOR DETECTION OF CORONARY ARTERY DISEASE/RISK ASSESSMENT: ASYMPTOMATIC (WITHOUT ISCHEMIC EQUIVALENT)			
General Patient Populations			
124.	Low global CHD risk		U (1)
125.	Intermediate global CHD risk ECG interpretable		I (2)
126.	Intermediate global CHD risk ECG uninterpretable		U (5)
127.	High global CHD risk		U (5)
STRESS ECHOCARDIOGRAPHY FOR DETECTION OF CORONARY ARTERY DISEASE/RISK ASSESSMENT: ASYMPTOMATIC (WITHOUT ISCHEMIC EQUIVALENT) IN PATIENT POPULATIONS WITH DEFINED COMORBID CONDITIONS			
New-Onset or Newly Diagnosed Heart Failure or Left Ventricular Systolic Dysfunction			
128.	No previous CAD evaluation <i>and</i> no planned coronary angiography		A (7)
Arrhythmias			
129.	Sustained VT		A (7)
130.	Frequent PVCs, exercise-induced VT, or nonsustained VT		A (7)
131.	Infrequent PVCs		I (3)
132.	Atrial fibrillation or other SVT		U (6)
Syncope			
133.	Low global CHD risk		I (3)
134.	Intermediate or high global CHD risk		A (7)
Elevated Troponin			
135.	Troponin elevation without symptoms or additional evidence of ACS		A (7)
STRESS ECHOCARDIOGRAPHY FOLLOWING PREVIOUS TEST RESULTS			
Asymptomatic: Previous Evidence of Subclinical Disease			
136.	Coronary calcium Agatston score <100		I (2)
137.	Low to intermediate global CHD risk Coronary calcium Agatston score between 100 and 400		U (5)
138.	High global CHD risk Coronary calcium Agatston score between 100 and 400		U (6)
139.	Coronary calcium Agatston score >400		A (7)
140.	Abnormal carotid intimal medial thickness (≥ 0.9 mm and/or the presence of plaque encroaching into the arterial lumen)		U (5)

Continued

**TABLE 14G-1 Echocardiography Appropriate Use: Transthoracic, Transesophageal, and Stress—cont'd**

STRESS ECHOCARDIOGRAPHY FOLLOWING PREVIOUS TEST RESULTS			Appropriateness Score (1-9)
Indication			
Coronary Angiography (Invasive or Noninvasive)			
141.	Coronary artery stenosis of unclear significance	A (8)	
Asymptomatic or Stable Symptoms, Normal Findings on Previous Stress Imaging Study			
142.	Low global CHD risk Last stress imaging study <2 years ago	I (1)	
143.	Low global CHD risk Last stress imaging study ≥2 years ago	I (2)	
144.	Intermediate to high global CHD risk Last stress imaging study <2 years ago	I (2)	
145.	Intermediate to high global CHD risk Last stress imaging study ≥2 years ago	U (4)	
Asymptomatic or Stable Symptoms with Abnormal Findings on Coronary Angiography or Previous Stress Study, No Previous Revascularization			
146.	Known CAD on coronary angiography or previous abnormal findings on stress imaging study Last stress imaging study <2 years ago	I (3)	
147.	Known CAD on coronary angiography or previous abnormal findings on stress imaging study Last stress imaging study ≥2 years ago	U (5)	
Treadmill Electrocardiographic Stress Test			
148.	Low-risk treadmill score (e.g., Duke)	I (1)	
149.	Intermediate-risk treadmill score (e.g., Duke)	A (7)	
150.	High-risk treadmill score (e.g., Duke)	A (7)	
New, Worsening, or Unresolved Symptoms			
151.	Abnormal findings on coronary angiography or abnormal findings on previous stress imaging study	A (7)	
152.	Normal findings on coronary angiography or normal finding on previous stress imaging study	U (6)	
Previous Noninvasive Evaluation			
153.	Equivocal, borderline, or discordant stress testing when obstructive CAD remains a concern	A (8)	
STRESS ECHOCARDIOGRAPHY FOR RISK ASSESSMENT: PERIOPERATIVE EVALUATION FOR NONCARDIAC SURGERY WITHOUT ACTIVE CARDIAC CONDITIONS			
Low-Risk Surgery			
154.	Perioperative evaluation for risk assessment	I (1)	
Intermediate-Risk Surgery			
155.	Moderate to good functional capacity (≥4 METs)	I (3)	
156.	No clinical risk factors	I (2)	
157.	≥1 clinical risk factor Poor or unknown functional capacity (<4 METs)	U (6)	
158.	Asymptomatic <1 year after normal findings on catheterization, noninvasive test, or previous revascularization	I (1)	
Vascular Surgery			
159.	Moderate to good functional capacity (≥4 METs)	I (3)	
160.	No clinical risk factors	I (2)	
161.	≥1 clinical risk factor Poor or unknown functional capacity (<4 METs)	A (7)	
162.	Asymptomatic <1 year after normal findings on catheterization, noninvasive test, or previous revascularization	I (2)	
STRESS ECHOCARDIOGRAPHY FOR RISK ASSESSMENT: WITHIN THREE MONTHS OF AN ACUTE CORONARY SYNDROME			
ST-Segment Elevation Myocardial Infarction			
163.	Primary PCI with complete revascularization No recurrent symptoms	I (2)	
164.	Hemodynamically stable, no recurrent chest pain symptoms or signs of heart failure To evaluate for inducible ischemia No previous coronary angiography since the index event	A (7)	
165.	Hemodynamically unstable, signs of cardiogenic shock, or mechanical complications	I (1)	

TABLE 14G-1 Echocardiography Appropriate Use: Transthoracic, Transesophageal, and Stress—cont'd

STRESS ECHOCARDIOGRAPHY FOR RISK ASSESSMENT: WITHIN THREE MONTHS OF AN ACUTE CORONARY SYNDROME		
Indication		Appropriateness Score (1-9)
Unstable Angina/Non-ST-Segment Elevation Myocardial Infarction		
166.	Hemodynamically stable, no recurrent chest pain symptoms or signs of heart failure To evaluate for inducible ischemia No previous coronary angiography since the index event	A (8)
ACS—Asymptomatic after Revascularization (PCI or CABG)		
167.	Before hospital discharge	I (1)
Cardiac Rehabilitation		
168.	Before initiation of cardiac rehabilitation (as a stand-alone indication)	I (3)
STRESS ECHOCARDIOGRAPHY FOR RISK ASSESSMENT: AFTER REVASCULARIZATION (PCI OR CABG)		
Symptomatic		
169.	Ischemic equivalent	A (8)
Asymptomatic		
170.	Incomplete revascularization Additional revascularization feasible	A (7)
171.	<5 years after CABG	I (2)
172.	≥5 years after CABG	U (6)
173.	<2 years after PCI	I (2)
174.	≥2 years after PCI	U (5)
Cardiac Rehabilitation		
175.	Before initiation of cardiac rehabilitation (as a stand-alone indication)	I (3)
STRESS ECHOCARDIOGRAPHY FOR ASSESSMENT OF VIABILITY/ISCHEMIA		
Ischemic Cardiomyopathy/Assessment of Viability		
176.	Known moderate or severe left ventricular dysfunction Patient eligible for revascularization Use of dobutamine only	A (8)
STRESS ECHOCARDIOGRAPHY FOR HEMODYNAMICS (INCLUDES DOPPLER DURING STRESS)		
Chronic Valvular Disease—Asymptomatic		
177.	Mild mitral stenosis	I (2)
178.	Moderate mitral stenosis	U (5)
179.	Severe mitral stenosis	A (7)
180.	Mild aortic stenosis	I (3)
181.	Moderate aortic stenosis	U (6)
182.	Severe aortic stenosis	U (5)
183.	Mild mitral regurgitation	I (2)
184.	Moderate mitral regurgitation	U (5)
185.	Severe mitral regurgitation Left ventricular size and function not meeting surgical criteria	A (7)
186.	Mild aortic regurgitation	I (2)
187.	Moderate aortic regurgitation	U (5)
188.	Severe aortic regurgitation Left ventricular size and function not meeting surgical criteria	A (7)
Chronic Valvular Disease—Symptomatic		
189.	Mild mitral stenosis	U (5)
190.	Moderate mitral stenosis	A (7)
191.	Severe mitral stenosis	I (3)
192.	Severe aortic stenosis	I (1)

Continued

TABLE 14G-1 Echocardiography Appropriate Use: Transthoracic, Transesophageal, and Stress—cont'd

STRESS ECHOCARDIOGRAPHY FOR HEMODYNAMICS (INCLUDES DOPPLER DURING STRESS)			Appropriateness Score (1-9)
	Indication		
193.	Evaluation of equivocal aortic stenosis Evidence of low cardiac output or left ventricular systolic dysfunction ("low-gradient aortic stenosis") Use of dobutamine only		A (8)
194.	Mild mitral regurgitation		U (4)
195.	Moderate mitral regurgitation		A (7)
196.	Severe mitral regurgitation Severe left ventricular enlargement or systolic dysfunction		I (3)
Acute Valvular Disease			
197.	Acute moderate or severe mitral or aortic regurgitation		I (3)
Pulmonary Hypertension			
198.	Suspected pulmonary hypertension Normal or indeterminate findings on resting echocardiographic study		U (5)
199.	Routine evaluation of patients with known resting pulmonary hypertension		I (3)
200.	Reevaluation of patient with exercise-induced pulmonary hypertension to evaluate response to therapy		U (5)
CONTRAST USE IN TRANSTHORACIC/TRANSESOPHAGEAL ECHOCARDIOGRAPHY OR STRESS ECHOCARDIOGRAPHY			
201.	Routine use of contrast All left ventricular segments visualized on non-contrast-enhanced images		I (1)
202.	Selective use of contrast ≥2 contiguous left ventricular segments are <i>not</i> seen on non-contrast-enhanced images		A (8)

ACS = acute coronary syndrome; APC = atrial premature contraction; CABG = coronary artery bypass grafting; CAD = coronary artery disease; CHD = coronary heart disease; ECG = electrocardiogram; METs = metabolic equivalents; MRI = magnetic resonance imaging; PCI = percutaneous coronary intervention; SVT = supraventricular tachycardia; TEE = transesophageal echocardiography; TTE = transthoracic echocardiography; TIA = transient ischemic attack; TIMI = Thrombolysis in Myocardial Infarction; UA = unstable angina; VPC = ventricular premature contraction; VT = ventricular tachycardia.

nomenclature such that the term "inappropriate" for ratings of 1 to 3 is now termed "rarely appropriate" and ratings of 4 to 6 are now termed "may be appropriate." Ratings of 7 to 9 remain "appropriate." However, the AUC for echocardiography⁸ have not yet been updated to reflect this change in terminology. The recent AUC documents for multimodality imaging in patients with stable ischemic heart disease and heart failure^{10,11} do conform to the updated terminology and provide criteria for the use of echocardiography in these conditions relative to the applications of the other imaging modalities (see Chapter 20G).

REFERENCES, 270

The chest x-ray (CXR) remains the most common radiographic examination and one of the most difficult to interpret. With careful evaluation, it yields a large amount of anatomic and physiologic information, but it is difficult and sometimes even impossible to extract all the information that it contains. The aims of this chapter are to review how the CXR is obtained, present a basic approach to its interpretation, and discuss and illustrate common and characteristic CXR findings in adults with cardiovascular disease. The major variables that determine what can be learned from the CXR include (1) the technical factors (milliamperage, kilovoltage, exposure duration) used in obtaining the CXR; (2) patient-specific factors (e.g., body habitus, age, physiologic status, ability to stand and to take and hold a deep breath); and (3) the training, experience, and focus of the interpreter.

TECHNICAL CONSIDERATIONS

The usual CXR study consists of a frontal view and a lateral view: a posteroanterior (PA) view of the patient while standing with the chest toward the recording medium and back to the x-ray tube and a lateral view of the patient while standing with the left side toward the film. For both views, the x-ray tube is positioned at a distance of 6 feet from the film, a 6-foot source-image distance (SID). The rationale for these conventions is based on physics; x-rays are created by inducing a high current across a diode, thereby generating electrons aimed at a metal target, the anode. When the electrons reach the target, x-ray photons are produced. The anode is made of special metals, rotates at high speed, and is housed in an oil-filled container, all to preserve the target and to ensure that production of the photons is uniform in number and energy without damage to the anode. The anode has an angled edge so that the x-rays emerge at essentially a right angle to the incoming electron beam. The x-rays are allowed to emerge from the tube housing only through a small opening, the focal spot. The smaller the focal spot, the higher the energy required to deliver a given number of photons. Also, the smaller the focal spot, the narrower the x-ray beam (i.e., the closer to a true point source), thus leading to improved imaging geometry. The ability of the x-rays to penetrate structures is determined by the combination of kilovoltage, milliamperage, and duration of exposure. These factors are also the major (but not sole) determinants of the radiation dose to the patient.^{1,2} In theory, x-rays emerge from the x-ray tube as a point source, remain parallel, and do not diverge from each other, and consequently there is no geometric distortion of structures as they pass through the body and are recorded on film. In reality, however, the x-rays form a cone-shaped beam. They diverge from the focal spot and become less parallel as the distance from the focal spot (i.e., SID) increases. When the incident x-rays interact with film or a digital screen, there is geometric distortion as a function of the distance from the midline of the x-ray beam and the distance of the structures from the film. If one imagines a wide-diameter structure, such as the thorax, that is perpendicular

to the center of the x-ray beam, the farther from the tube that the object is, the more parallel the x-rays that penetrate it (**Figs. 15-1** and **15-2**). Conversely, the closer the object and film to the x-ray tube, the more the incident x-rays must diverge to cover the edges of the object. Thus the farther an object is from the source, the less geometric distortion that is encountered. The greater the distance from the source, however, the more energy that must be applied to penetrate the object to be imaged and to expose the x-ray recording medium. That is, in simple terms, resolution is improved by increasing the SID, but tube energy and therefore exposure to the patient must also be increased as the SID increases. To balance these opposing concerns, a standard convention has been developed; routine standing CXRs are obtained with an SID of 6 feet. X-rays are blocked from the film or other recording medium to varying degrees by various structures, which leads to shades of gray that allow discrimination between the heart, which is fluid filled and relatively impervious to x-rays, and the air-filled lung parenchyma, which blocks few x-rays. The exposure that the patient receives is a function of the strength and duration of the current applied to the x-ray tube (or more precisely and accurately, a function of the number, strength, and duration of the x-ray photons produced—milliamperage, kilovoltage, and milliseconds), size of the focal spot, distance from the tube to the patient, and degree to which the x-rays are blocked and scattered within the patient. Most patient exposure is not a result of the x-rays that penetrate but rather those that interact with body structures and are slowed and changed and, in the process, deposit residual energy in tissue. This process is what is broadly referred to as scatter. As the amount of tissue that attenuates photons increases, the amount of energy deposition within the patient will increase. Patients who are very thin will require an inherently lower x-ray dose to achieve diagnostically satisfactory deposition of x-ray photons on an imaging medium and will have less deposition of energy within the body. In patients who are obese, a higher x-ray dose will be necessary to penetrate the patient and produce a diagnostic exposure. The increased soft tissue in these patients also causes more dispersion of the x-ray beam and results in a higher dose. Scatter not only leads to deposition of energy in the patient but also deposits energy in surrounding structures, including personnel, if they are close to the patient (as with fluoroscopy), and the recording medium. That is, the film or digital plate is altered not only by the incident x-rays intended to produce the image (i.e., signal) but also by scatter, which does not reflect anatomic structures but will detract from the resolution of these structures (i.e., noise). The more scatter deposited on the recording medium, the more the image quality is denigrated and the worse the resolution—the signal-to-noise ratio is decreased. This is why the resolution of CXRs is worse in larger than in thinner patients when all other factors remain constant. Several additional practical considerations are related to the physics of CXRs. The standard CXR is obtained with deep inspiration and the patient facing the film. If patients are unable to stand, CXRs are generally obtained with the patient's chest toward the tube and back toward the film, the anteroposterior (AP) position. With the standard PA view, the heart appears smaller and its size and contour are more accurately depicted than on an AP view because the SID is larger and the heart is closer to the

recording medium. With AP views, as with portable films, there is a resultant greater divergence of the x-rays because the heart lies relatively anteriorly (and thus is farther from the film) and the SID is short. Similarly, on a standard lateral film, the right ribs appear larger than the left ribs (Fig. 15-2B). In both cases this effect occurs because a structure is farther from the film. As a result there is increased divergence of the x-rays from the midline point source and relative magnification. Therefore the side of an effusion can generally be delineated on a lateral radiograph by determining whether the effusion is associated with the side on which the ribs appear larger or the side on which they appear smaller (see Fig. 15-2B).

Portable CXRs have inherent practical limitations. Most are obtained with patients positioned supine or semisupine. Depth of inspiration is therefore likely to be decreased in comparison to an erect film, which

makes the heart appear relatively larger and provides less optimal visualization of the lungs because they are not optimally expanded. Furthermore, portable radiographs are invariably taken as AP views and the SID is less than 6 feet, for obvious practical reasons, including space constraints and the limited power of portable x-ray machines, which require longer exposure time and consequently are subject to increased cardiac and respiratory motion and decreased resolution. Inherently, then, resolution is poorer with portable radiographs, thus making them less accurate and useful. In addition, the radiation dose to both patients and personnel is generally greater.

Portable CXRs are most useful for answering relatively simple mechanical questions, such as whether a pacemaker or implantable cardioverter-defibrillator (ICD) is properly positioned (Fig. e15-1), whether an endotracheal tube is in the correct location, and whether the mediastinum is midline.²⁻⁴ They are not generally good at providing physiologic or complex anatomic information, and there are questions that *cannot* be answered accurately from a portable CXR. If the CXR is obtained with the patient in less than an upright position, it is impossible to exclude even a sizable pneumothorax or pleural effusion. Because of the patient's position, shorter SID, and limited tube output, it is impossible to accurately evaluate heart size and contour or status of the pulmonary vasculature. Although portable CXRs may be convenient and provide some information, they should be performed only in limited situations when clearly needed to answer specific questions.^{3,4}

FIGURE 15-1 Position of the patient in relation to the source-image distance (SID) between the x-ray source (focal spot) and the recording medium. The closer the patient to the source, the greater the x-ray divergence and resulting geometric distortion.

FIGURE 15-2 Standard upright chest radiographs of a 74-year-old man who has undergone aortic valve replacement. **A**, PA view showing the median sternotomy wires, a left pleural effusion (arrow), and a normal pulmonary vascular pattern. **B**, Lateral view. Note that the right ribs (white arrow) are magnified in comparison to the left (black arrow), and the effusion can be localized to the left. Also note that the gastric air bubble is displaced inferiorly (PA view) and anteroinferiorly (lateral view), indicative of an enlarged left ventricle.

Image Recording and Radiation Exposure

Until the turn of the last century, all CXRs were recorded on high-resolution radiographic film. With optimal technique and a cooperative patient who can hold a deep inspiration, the result is a study that clearly and accurately depicts very small structures, such as the contour of small pulmonary arteries. With radiographic film, the incident x-rays (and scattered photons) alter the silver iodide crystals in an emulsion. When the film is developed, these alterations produce an image reflecting the extent to which the x-rays have interacted with specific areas of the film. There is inherently very high resolution of structures because of the small size of the silver iodide crystals and their sensitivity to incident x-ray photons. This has changed with the use of computed radiography (CR) and digital radiography (DR), filmless forms of radiography. DR is the direct recording of images by digital means, without analog-to-digital conversion, onto a panel that allows direct recording of incident photons of different energy and frequency on a flat digital panel, without the use of a permanent film or analog-to-digital conversion. This information is then directly downloaded and can be viewed and postprocessed. CR is similar,

but instead of a direct connection to the radiology information system (RIS), the image is recorded onto a reusable panel, which is then "read" into the system and downloaded. Currently, CR is less expensive, and because it does not inherently require direct connection to the RIS, it is widely used for portable imaging. As the cost of flat panels for DR decreases and the ability to download images wirelessly improves, CR is gradually being replaced. The inherent resolution with both is very similar to that of conventional radiographic film, but the elimination of analog-to-digital conversion eliminates some noise and thus the overall resolution tends to be as good as with conventional film-screen radiographs.⁵⁻¹⁶ DR has additional advantages. First, digital technology leads to an image that is posted immediately on the RIS, without going through the step of developing the film. Using picture archiving and communication systems (PACS), digital images are then available as soon

FIGURE e15-1 **A**, Portable chest radiograph demonstrating the location of a guidewire (used for placement of a peripherally inserted central catheter) in a left-sided SVC. **B**, Venogram confirming the variant left SVC and absent left innominate vein.

as they are downloaded for review at any location where a PACS-enabled workstation is present. This adds speed and availability and obviates the problem of lost films—all films are digitally archived—and the need to go to a remote location to review a film.^{17,18} The dose to an individual patient may or may not be lower as a function of patient factors and the specific imaging system.^{8,15,17} Overall radiation exposure to patients, however, is decreased because the need to repeat films as a result of inadequate positioning or exposure is substantially eliminated: with DR, the image can be postprocessed to alter the relative density (window and level), and magnification and even the area included can be altered without re-exposing the patient. This provides the ability to add substantial information (Fig. e15-2). Storage of conventional radiographic films is relatively straightforward, although it is time and space intensive. Storage of digital images, even though initially more complex, eliminates many of the major problems encountered with storage of standard radiographs. Integration with a system-wide electronic medical record allows improved access and use in comparison to what was available even a decade ago.^{17,18}

The radiation exposure to the patient should always be kept in mind when any radiographic study is ordered or performed. The complexity of diagnostic radiation in the general population limits obtaining clear answers. The radiation necessary for PA and lateral CXRs is usually minimal in terms of radiation effects, in both the dose of a single study (generally <1 mSv) and the cumulative dose of repeated CXRs. In pregnant women and children, radiation exposure is always a concern because of the long latency period for radiation-induced cancer.¹⁹⁻²¹ Concerns have been raised that exposure of the population has increased over the last few decades, largely because of the use of high-tech imaging such as computed tomography (CT), radionuclide studies, and cardiac interventional procedures. The contribution from conventional imaging procedures such as CXRs is small, but the precise relationships between individual exposures and cumulative effect are not known. Basically, all diagnostic imaging carries at least a small theoretical risk, even at very low doses, so any use must balance this possible risk against the probable benefit; each CXR should be ordered with care.^{2,3,20}

NORMAL CHEST RADIOGRAPH

Interpreting standard PA and lateral CXRs is a daunting task. The amount of information present is huge, and there are countless relevant variables that must be evaluated: the soft tissues, bones and joints, pleura, lungs and major airways, pulmonary vasculature, mediastinum and its contents, heart (and specifically its chambers), the aorta, and areas below the diaphragm and above the thorax. It is imperative to take a systematic and standardized approach, based first on assessment of the anatomy, then the physiology, and finally the pathology. Any approach must be based on an understanding of what is normal.^{22,23} On the standard PA CXR, the overall heart diameter is normally less than half the transverse diameter of the thorax (Fig. 15-3). The heart overlies the thoracic spine, roughly 75% to the left and 25% to the right of the spine. The mediastinum is narrow superiorly, and normally the descending aorta can be defined from the arch to the dome of the diaphragm on the left. The pulmonary hila are seen below the aortic arch, slightly higher on the left than on the right. On the lateral CXR (Fig. 15-4), the left main pulmonary artery

FIGURE 15-3 Frontal projection of the heart and great vessels. **A**, Left and right heart borders in the frontal projection. **B**, A line drawing in the frontal projection demonstrates the relationship of the cardiac valves, rings, and sulci to the mediastinal borders. A = ascending aorta; AA = aortic arch; Az = azygos vein; LA = left atrial appendage; LB = left lower border of the pulmonary artery; LV = left ventricle; PA = main pulmonary artery; RA = right atrium; RV = right ventricle; S = superior vena cava; SC = subclavian artery.

can be seen coursing superiorly and posteriorly relative to the right. On both frontal and lateral views, the ascending aorta (aortic root) is normally obscured by the main pulmonary artery and both atria. The location of the pulmonary outflow tract is usually clear on the lateral film.

Cardiac Chambers and Aorta

On a normal CXR it is not usually possible to define individual cardiac chambers. It is imperative, however, to know their normal position and to determine whether the size and location of each chamber and the great vessels are within the normal range. On the PA view, the right contour of the mediastinum contains the right atrium and the ascending aorta and superior vena cava (SVC). If the azygos vein is enlarged secondary to right-sided heart failure or SVC obstruction (Fig. e15-3), it may also be visible. The right ventricle, as is clear from cross-sectional imaging (Fig. 15-5), is located partially overlying the left ventricle on both frontal and lateral views.²⁴ The left atrium is located just inferior to the left pulmonary hilum. Individuals with normal anatomy have a concavity at this level, the location of the left atrial (LA) appendage. The atrium constitutes the upper portion of the posterior contour of the heart on the lateral CXR but cannot normally be separated from the left ventricle. The left ventricle constitutes the prominent, rounded apex of the heart on the frontal view and the sloping inferior portion of the mediastinum on the lateral view (see Figs. 15-3 and 15-4).

The apex is often not clearly delineated for a reason related to x-ray attenuation. The heart is distinguishable from the lungs because it contains water-density blood rather than air. Because blood attenuates x-rays to a greater extent than air does, the heart appears relatively white (although less so than calcium-containing bones) and the lungs relatively black (less so than the edges of the CXR, where there is only air and no interposed tissue). A fat pad of varying thickness surrounds the apex of the heart (Figs. 15-6 and e15-4). Fat has a density greater than that of air and marginally less than that of blood. As it covers the ventricular apex, the fat pad is relatively thick and dense. As it thins out toward the left lateral chest wall, it is progressively less dense, which explains the hazy, poorly margined appearance of the apex. Similarly, a fat pad may be seen on the lateral CXR as a wedge-shaped density overlying the anterior aspect of the left ventricle (see Figs. 15-6 and e15-4). The pericardial sac cannot normally be defined (Fig. 15-7). The borders of the cardiac silhouette are normally moderately but not completely sharp in contour. Even though the exposure time for a CXR is very short (<100 milliseconds), normal

FIGURE e15-2 **A, B**, PA and lateral digital chest radiographs with different windows and leveling. **A**, With a pulmonary window and leveling, the lung fields, including the pulmonary vasculature, are well visualized but the mediastinal structures are not well defined. Note also flattening of the diaphragms and increased lung lucency, indicative of chronic obstructive pulmonary disease. **B**, Rewindowed, the mediastinal structures are now well seen and show a dilated, calcified aortic root and descending thoracic aorta. Pulmonary vascularity cannot be defined in these images. **C**, CT scan at the level of the aortic root and arch confirming the marked ectasia of the entire thoracic aorta.

FIGURE e15-3 Radiographs of a 39-year-old renal transplant patient. **A**, Normal PA and lateral images, except for prominence in the azygos vein region (arrow). **B**, Right innominate venogram demonstrating an occluded SVC and markedly enlarged azygos vein draining below the diaphragm.

FIGURE e15-4 Chest radiographs of a 70-year-old woman with rheumatic heart disease and combined aortic stenosis and mitral stenosis. Her PCWP is 30 mm Hg. **A**, PA view. There is evidence of chronically elevated pulmonary venous pressure with moderate (not marked) pulmonary vascular redistribution. Moderate LV enlargement and prominence of the LA appendage are present. **B**, Lateral view. Note enlargement of the left ventricle, which is extending below the diaphragm and compressing the gastric bubble (arrowheads). Also note the apical fat pad, seen as the hazy density on the frontal view (**A**, arrow) and as the anterior, retrosternal, well-delineated, wedge-shaped density on the lateral view (**B**, arrow).

FIGURE 15-4 **A**, Lateral chest radiograph. **B**, Superimposed anatomic drawing of the cardiac chambers and great vessels. **C**, Diagram of the lateral projection of the heart showing the position of the cardiac chambers, valve rings, and sulci. Arrows indicate the direction of blood flow. A = aorta; PA = pulmonary artery; RAA = right atrial appendage; RV = right ventricle.

cardiac motion is usually sufficient to cause minor haziness of the silhouette. If a portion of the heart border does not move (as with a left ventricular [LV] aneurysm) the border may be unusually sharp (**Fig. e15-5**). The aortic arch is generally visible because the aorta courses posteriorly and is surrounded by air. Most of the descending aorta is also visible. The position and the size of each can easily be evaluated (see **Figs. 15-6** and **e15-2**) on the frontal and lateral views.

Lungs and Pulmonary Vasculature

Lung size varies as a function of inspiratory effort, age, body habitus, water content, and intrinsic pathologic processes. For example, because lung distensibility decreases with age, the lungs normally appear subtly but progressively smaller as patients age, even with maximal inspiratory effort. As lung size decreases, the heart appears relatively slightly larger, although in adults the heart does not normally exceed half the transverse diameter of the chest on a good-quality PA CXR unless true cardiomegaly is present. Also, with increasing left ventricular end-diastolic pressure (LVEDP), as in heart failure, or increasing LA pressure, as in mitral stenosis, interstitial fluid in the lungs increases, lung compliance decreases, and therefore expansion as seen on a CXR is lessened. In patients with chronic obstructive pulmonary disease, with or without bullae, the lungs appear larger and blacker, the diaphragms may appear flattened, and relative heart size decreases, with the heart often appearing small or normal in size, even in the presence of cardiac dysfunction (see **Fig. e15-2**). It is important to recognize that evident enlargement of the cardiac silhouette on a CXR has many possible explanations, including true enlargement of the heart overall, dilation of one or more chambers, pericardial fluid (see **Fig. 15-5**), or other explanations as noted.

In normal subjects, pulmonary vascularity has a predictable pattern. The pulmonary arteries are usually easily visible centrally in the hila and progressively less so more peripherally. Centrally, the main right and left pulmonary arteries are difficult to quantify unless they are grossly enlarged because

FIGURE 15-5 **A**, Radiographs of an older man with biventricular hypertrophy (note the boot-shaped heart on the PA view, arrows on the lateral view), marked pulmonary vascular redistribution (note the haziness and loss of definition of margins of the pulmonary vessels throughout), and right pleural effusion. **B**, CT scan confirming biventricular hypertrophy, with the right ventricle (RV) larger than the left ventricle (LV), enlargement of the right atrium (RA), and right pleural effusion.

FIGURE e15-5 Chest radiographs of a 53-year-old woman with coronary artery disease and heart failure following a large anterolateral MI. **A**, Frontal portable view suggesting cardiomegaly and heart failure. The sharp horizontal contour of the left ventricle is suggestive of an anterior wall aneurysm. **B, C**, PA and lateral views after revascularization and aneurysmectomy demonstrating persistence of an abnormal contour of the left ventricle, consistent with recurrent aneurysm, and clips on side branches of the saphenous vein graft to the right coronary artery.

FIGURE 15-6 A, PA and lateral chest radiographs showing marked aortic root dilation (yellow arrows), a mass versus an artifact in the lingula in the frontal (PA) view (white arrow), and slight haziness of the cardiac apex. There is a prominent apical fat pad on the lateral view (black arrows). B, CT scan showing marked dilation of the aortic root (arrow), a mass in the lingula that is poorly seen on radiographs, and a prominent apical fat pad (thick arrow).

FIGURE 15-7 Chest radiographs of a 45-year-old man with calcific pericarditis. A, The PA view is essentially normal. B, A lateral view demonstrates thin, irregular calcification of the pericardium around the left ventricular contour.

they lie within the mediastinum (see Figs. 15-3 and 15-4). If the lung is thought of in three zones, the major arteries are central; the clearly distinguishable mid-sized pulmonary arteries (third- and fourth-order branches) are in the middle zone; and the small arteries and arterioles, which are normally below the limit of resolution, are in the outer zone.

The visible small and mid-sized arteries (midzone) have sharp, clearly definable margins because of the sharp border between water-density and air-density structures. On a standard, standing frontal (PA) CXR, the arteries in the lower zone are larger than those in the upper zone, at an equal distance from the hila, because of the effect of gravity on the normal, low-pressure lung circulation; gravity leads to slightly greater intravascular volume at the lung bases than in the upper zones. This effect of gravity on the distribution of normal intravascular lung volume is reflected in a normal perfusion lung scan. Because the radionuclide is generally administered with the patient supine, there is a greater concentration posteriorly than anteriorly, as confirmed by the count rates. Conversely, if the patient is sitting or standing when the radionuclide is injected, the count rate is greater at the lung base than at the apices.

The angles that the lungs make with the diaphragm are normally sharp and clearly seen bilaterally on frontal and lateral views because the pleura is usually tightly applied to (not separated from) the ribs. The contour that the inferior vena cava (IVC) makes with the heart is clearly seen on the lateral CXR (see Fig. 15-2B). Its relationship to the rest of the cardiac silhouette varies markedly, depending on minor degrees of rotation of the patient; that is, the IVC lies on the right of the mediastinum and posterior to the contour of the heart. This contour is made up of the left atrium and ventricle, which lie toward the left side of the thorax. If the patient is placed laterally with the left side against the film, the right is relatively slightly magnified in comparison to the left (see Figs. 15-2B and 15-5). If the patient rotates minimally anterior or posterior to true lateral, the relationship between the IVC and left-sided contours changes substantially. This anatomic relationship is important to understand because in the past a formula was used (the Riegler sign) to determine LV enlargement as a function of its relationship to the IVC. This sign, although sometimes still referenced, is not accurate and should not be relied on.²⁵

Normal Variations

Anatomic variables and aging present challenges in the evaluation of CXRs, in addition to those posed by decreased lung compliance. The aorta and great vessels normally dilate and become more tortuous and prominent with increasing age, thereby leading to widening of the superior mediastinum. As noted, the heart appears larger because of decreasing lung compliance, although unless true cardiac disease is present, its diameter remains less than half the transverse diameter of the chest on a PA view. There are additional important anatomic considerations. Patients who are obese may not be able to fully expand their lungs, thus making a normal heart appear slightly larger. In patients

with pectus excavatum the heart may appear enlarged on the frontal view, but this is explained by the narrow AP diameter seen on the lateral view. There may also be lack of definition of the right heart border on the frontal view because of compression by the sternum (Fig. e15-6). Marked kyphosis, as may occur with osteoporotic

FIGURE e15-6 Routine chest radiographs of a healthy 37-year-old woman. Note the hazy right mediastinal silhouette on the frontal view caused not by cardiac or pulmonary abnormalities but by pectus excavatum (*arrow*), as seen on the lateral view. Note also the normal pulmonary vascular pattern.

collapse of vertebral bodies or scoliosis, can also cause the heart or mediastinum to look abnormal. It is thus important to evaluate the spine and other bony structures systematically when evaluating a CXR. Delineation of all anatomic abnormalities is beyond the scope of this chapter. For an in-depth discussion, *Fraser and Pare's Diagnosis of Diseases of the Chest*,²⁶ although last revised more than a decade ago, remains a useful reference.

THE CHEST RADIOGRAPH IN HEART DISEASE

Overview

A systematic approach to the evaluation of a CXR is imperative to distinguish normal from abnormal and to define the underlying pathology and pathophysiology, and each person must develop his or her own system. The first step is to define which type of CXR study is being evaluated—PA and lateral, PA alone, or an AP view (either portable or one obtained in the AP view because the patient is unable to stand). The next step is to determine whether previous CXRs are available for comparison, and if they are, they should be reviewed routinely; many abnormalities are put into appropriate perspective by determining whether they are new. Common examples are a prominent aortic arch, visible major fissure related to a previous inflammatory process, or widened superior mediastinum related to aortic ectasia, a substernal thyroid, or an enlarged azygous vein (see [Figs. e15-2](#) and [e15-3](#)).

Any system must incorporate a routine that includes a deliberate attempt to look at areas that are easily ignored. Such areas include the thoracic spine, neck (for masses and tracheal position), costophrenic angles, lung apices, retrocardiac space, and retrosternal space. These areas are evaluated to define mediastinal position, cardiac and aortic situs, and the presence of pleural effusions, scarring, or diaphragmatic elevation. It is logical to evaluate the lung fields next. This should involve a careful search for infiltrates or masses, even when the primary concern is cardiovascular abnormalities; many people with coronary artery disease have a history of tobacco abuse and thus are at increased risk for lung malignancies (see [Fig. 15-6](#)).

Cardiovascular diseases cause various and complex changes in the appearance of the CXR. The overall size of the cardiac silhouette (see [Fig. 15-5](#)), its position (see [Fig. e15-5](#)), and the location of the ascending and descending aorta must be specifically evaluated. Dextrocardia and a right descending aorta are rare, particularly in adults, but are easy to check for and are important to recognize because of their association with congenital cardiac and abdominal situs abnormalities. It is also important to look at the site and position of the stomach. This information can be used to differentiate between a high diaphragm and a pleural effusion (see [Fig. 15-2](#)). Cardiomegaly, accurately judged by the heart diameter exceeding half the diameter of the thorax on a PA CXR, is a common but nonspecific finding²⁵⁻²⁸ (see [Figs. 15-5](#) and [e15-5](#)).

Lungs and Pulmonary Vasculature

Evaluation of the pulmonary vascular pattern is difficult and imprecise but very important. As noted, the pattern varies with the patient's position (erect versus supine) and is altered substantially by underlying pulmonary disease. It is best to define pulmonary vascularity by looking at the middle zone of the lungs (i.e., the third of the lungs between the hilar region and the peripheral

region laterally) and comparing a region in the upper portion of the lungs with a region in the lower portion, at equal distances from the hilum. Vessels should be larger in the lower part of the lung and sharply margined in both the upper and lower zones. In normal individuals, the vessels taper and bifurcate and are difficult to define in the outer third of the lung. They normally become too small to be seen near the pleura (see [Figs. e15-3](#) and [e15-5](#)).

Two distinct patterns of abnormality are recognizable. When PA flow is increased, as in patients with a high-output state (e.g., pregnancy, severe anemia as in sickle cell disease, hyperthyroidism) or left-to-right shunt, the pulmonary vessels are more prominent than usual in the periphery of the lung ([Fig. e15-7](#)). They are uniformly enlarged and can be traced almost to the pleura, but their margins remain clear. In contrast, in patients with elevated pulmonary venous pressure, the vessel borders become hazy, the lower zone vessels constrict, and the upper zone vessels enlarge; vessels become visible farther toward the pleura, in the outer third of the lungs ([Fig. 15-8](#); see also [Fig. 15-5](#)). With increasing LVEDP or LA pressure, interstitial edema increases and ultimately pulmonary edema develops ([Fig. 15-9](#)). There is usually a reasonably good correlation between the pulmonary vascular pattern and pulmonary capillary wedge pressure (PCWP). At a PCWP of less than 8 mm Hg, the vascular pattern is normal. As PCWP increases to 10 to 12 mm Hg, vessels in the lower zone appear equal in diameter to or smaller than vessels in the upper zone. At pressures of 12 to 18 mm Hg, the vessel borders become progressively hazier because of increasing extravasation of fluid into the interstitium. This effect is sometimes evident as Kerley B lines, which are horizontal, pleural-based, peripheral linear densities. As PCWP increases above 18 to 20 mm Hg, pulmonary edema occurs, with interstitial fluid present in sufficient amount to cause the classic perihilar "bat wing" appearance (see [Fig. 15-9](#)).

Again, these typical appearances may be altered for various reasons. In patients with extensive pulmonary fibrosis or multiple bullae, the vascular pattern is abnormal at baseline, and as PCWP increases, it does not change in predictable ways as definable on a CXR. In patients with chronic heart failure, there are chronic changes in the pulmonary vascular pattern that do not correlate with the changes that occur in patients with normal LV pressure at baseline.²⁷⁻²⁹ For example, a patient with chronic heart failure and elevation of LVEDP to 25 to 30 mm Hg may have a normal pulmonary vascular pattern or moderate rather than marked redistribution (see [Figs. 15-5](#) and [e15-4](#) and compare with [Fig. 15-9](#)). In general, heart size increases over time as LVEDP and pulmonary vascular redistribution increase. If the pulmonary edema is independent of LV dysfunction, however, as may occur at a high altitude or following cerebral trauma, the size

FIGURE 15-8 Chest radiographs of a 59-year-old woman with a history of rheumatic heart disease and mitral stenosis. **A**, PA view demonstrating an enlarged cardiac silhouette with suggestion of a double density seen through the heart (LA enlargement), prominent convexity of the LA appendage (small arrow), and a slightly elevated cardiac apex (large arrow) suggestive of RV (rather than LV) enlargement. There is significant elevation of pulmonary venous pressure. **B**, The lateral view confirms marked RV (arrow) and LA (small arrows) enlargement. Note filling in of the retrosternal airspace. AV = atrioventricular.

FIGURE e15-7 Chest radiograph of a 47-year-old asymptomatic woman with a small atrial septal defect. The PA view shows a normal cardiac contour with mild pulmonary vascular plethora at the periphery of the lung fields.

FIGURE 15-9 Patient with acute pulmonary edema. Note the engorged hila bilaterally with the typical pattern of pulmonary edema on the right. Also note the intra-aortic counterpulsation balloon with a radiopaque tip at the top of the descending aorta (small arrow) and the balloon expanded in the aorta below it (large arrow).

of the heart may remain normal. A more frequently encountered disparity is found in the setting of an acute, large transmural myocardial infarction (MI); the heart is usually minimally or mildly enlarged despite a marked increase in LVEDP (see Fig. 15-9). Regardless of these limitations, it is important to evaluate the pulmonary vascular pattern routinely because it can provide a great deal of information.

Cardiac Chambers and Great Vessels

After assessing overall heart size and the pulmonary vascular pattern—as a reflection, in general, of left-sided heart physiologic status—the individual chambers should be examined. As noted, it is not possible to define individual chambers clearly on a normal CXR (see Figs. 15-3 and 15-4), and when the cardiac silhouette is enlarged, it is most often related to biventricular failure with no definable individual chamber enlargement. In acquired valvular disease and in many types of congenital heart disease, however, individual chamber enlargement is present and crucial to CXR (and often clinical) diagnosis.^{22,23,29-32} This information is now readily available with other more expensive, but more accurate imaging modalities—echocardiography, cardiac magnetic resonance (CMR), and cardiac CT (see Chapters 14, 17, and 18).^{32,33} CXRs have several advantages, however: (1) they allow fairly straightforward assessment of current status and changes over time, (2) they are routinely and readily available, (3) they are inexpensive, and (4) they carry a low radiation dose.^{34,35}

Right Atrium

Right atrial enlargement is essentially never isolated except in the presence of congenital tricuspid atresia or the Ebstein anomaly.³⁶ Both are rarely encountered, even in the pediatric age group. The right atrium may dilate in patients with pulmonary hypertension or tricuspid regurgitation, but right ventricular (RV) dilation usually predominates and prevents definition of the atrium. The right atrial contour blends with that of the SVC, right main pulmonary artery, and right ventricle. Thus it is almost impossible to define in adults, and it is pointless to try (see Fig. 15-5).

Right Ventricle

The classic signs of RV enlargement are a boot-shaped heart and filling in of the retrosternal airspace.²⁴ The former is caused by transverse displacement of the apex

of the right ventricle as it dilates (Fig. 15-10; see also Fig. 15-8). In adults it is rare for the right ventricle to dilate without LV dilation, so this boot shape is not often obvious. It is most commonly seen as an isolated finding in congenital heart disease, typically tetralogy of Fallot. As the right ventricle dilates, it expands superiorly, as well as laterally and posteriorly, thus explaining the well-margined increase in density in the retrosternal airspace (Fig. e15-8). Classic teaching is that on a lateral CXR in normal patients, the soft tissue density is confined to less than one third the distance from the suprasternal notch to the tip of the xiphoid. If the soft tissue fills in by more than one third in the absence of other explanations—such as lymphadenopathy, lymphoma, thymoma, marked main pulmonary artery (Fig. e15-9), or aortic root dilation (see Figs. 15-6 and e15-2)—it is a reliable indication of RV enlargement. The most common cause of increased retrosternal soft tissue, however, is previous median sternotomy, with resultant scarring and haziness of this region (see Fig. e15-5). RV enlargement is most often seen in patients with mitral valve disease secondary to pulmonary hypertension (see Figs. 15-10, e15-7, and e15-8). Less commonly, it is the result of primary pulmonary hypertension or chronic pulmonary emboli (see Chapter 74).

Left Atrium

Several classic signs define LA enlargement.^{22,35} The first is dilation of the LA appendage, seen as a focal convexity where there is normally a concavity between the left main pulmonary artery and the left border of the left ventricle on the frontal view (see Fig. e15-8). Second, because of its location, as the left atrium enlarges, it elevates the left main stem bronchus. In so doing it widens the angle of the carina. Third, as the left atrium enlarges posteriorly, it may cause focal bowing of the middle to low thoracic aorta toward the left (see Fig. e15-8). This bowing is distinguishable from the tortuosity seen with progressive atherosclerosis, which involves the descending thoracic aorta in its upper portion or diffusely. Fourth, with marked LA enlargement, a double density can be seen on the frontal view because the left atrium projects laterally toward the right and posteriorly and the discrete outline of the blood-filled left atrium is surrounded by air-filled lung (see Figs. 15-10 and e15-8). Finally, on the lateral CXR, LA enlargement appears as a focal, posteriorly directed bulge (see Figs. 15-8B and 15-10B).

Definable LA enlargement is the hallmark of mitral valve disease, and isolated LA enlargement in adults is most often seen in those with mitral stenosis (see Chapter 63). In mitral stenosis the left atrium dilates progressively over time (because of a progressive increase in pressure in this low-pressure left-sided chamber), there is consequent progressive evidence of pulmonary vascular redistribution, often with Kerley B lines, and eventually the right ventricle becomes dilated and enlarged. The left ventricle, however, usually remains normal in size (see Figs. 15-8, 15-10, and e15-8). In contrast, in mitral regurgitation, with increased volume in the left atrium and

FIGURE 15-10 Chest radiographs of a 60-year-old woman with severe mitral stenosis. **A**, PA view showing enlargement of the left atrium (arrowheads), prominence of the hilar vessels, and pulmonary vascular redistribution. The transverse angle of the apex suggests RV enlargement (arrow). **B**, Lateral view confirming RV enlargement with filling in of the retrosternal airspace. Note also the marked LA enlargement (arrows).

FIGURE e15-8 Chest radiographs of a 39-year-old Asian woman with rheumatic mitral stenosis. **A**, Frontal view showing normal heart size, mild vascular redistribution, and marked focal enlargement of the left atrium (*small arrow*), which extends to the right of midline (*large arrow*). There is elevation of the left main stem bronchus. **B**, Lateral view showing a dilated right ventricle with filling in of the retrosternal airspace. The left ventricle is normal in size and contour.

FIGURE e15-9 Chest radiographs of a 56-year-old asymptomatic woman with incidentally discovered pulmonic stenosis. **A**, PA view showing marked enlargement of the main pulmonary trunk extending into the left main pulmonary artery (*arrow*). **B**, Lateral view confirming prominence of the pulmonary outflow tract and main and left pulmonary arteries (*arrows*).

ventricle, *both* dilate over time (**Fig. 15-11**). The pattern of pulmonary vascular redistribution is more variable in mitral regurgitation than in mitral stenosis, as is RV dilation. It is also important to note mitral annulus calcification (**see Chapter 76**); this finding is common but does not have a strong association with valvular dysfunction, although it may be associated with premature coronary artery disease (**Fig. e15-10**).³⁷

Left Ventricle

LV enlargement is characterized by a prominent, downwardly directed contour of the apex, as distinguished from the transverse displacement seen with RV enlargement. On a PA CXR, the overall cardiac contour is also usually enlarged, although this is a nonspecific finding. It is also important to evaluate the left ventricle on a lateral CXR. Here it is seen as a posterior bulge, below the level of the mitral annulus (**Fig. 15-12**). It may also be seen pushing the gastric bubble inferiorly (see **Figs. 15-5A** and **e15-4**). Such LV enlargement is an illustration of manifestations of cardiac disease outside the usual confines of the chest and is indicative of the value of looking at the entire CXR.

Focal LV enlargement in adults is a common manifestation of aortic insufficiency (often with aortic root dilation; see **Fig. 15-12**) or mitral regurgitation (with LA dilation; see **Fig. 15-11**). In contrast, because aortic stenosis is characterized by LV hypertrophy rather than dilation, the left ventricle is dilated on the CXR only when aortic stenosis is accompanied by LV failure.^{22,38-40}

FIGURE 15-11 Chest films of a 78-year-old woman with pure mitral regurgitation and atrial fibrillation. **A**, PA view showing enlargement of the left atrium and left ventricle with mild pulmonary vascular redistribution. **B**, Lateral view confirming these findings. Arrowheads indicate the prominent LV contour.

FIGURE 15-12 Chest radiographs of a 63-year-old man with chronic aortic regurgitation. **A**, PA view showing downward displacement of the apex (arrow), suggestive of LV enlargement. There is prominence and enlargement of the ascending aorta, which has created a convex right border of the mediastinum. **B**, Lateral view showing prominent LV enlargement (arrowheads). The aortic root is markedly enlarged in the retrosternal airspace but is separate from the sternum (in contrast to the findings with RV enlargement; see **Fig. 15-10B**).

Pulmonary Arteries

The main pulmonary artery can appear abnormal in many clinical settings. In the presence of pulmonic stenosis, the main pulmonary artery and left main pulmonary artery dilate (see **Fig. e15-9**). Such dilation is thought to be caused by a jet effect directed through the stenotic valve to the main pulmonary artery and the left main pulmonary artery, which is directly in line with it. The right main pulmonary artery comes off at a fairly sharp angle and is not generally affected by the jet from the stenotic valve. The dilation is seen as a prominent left hilum on the frontal view and a prominent pulmonary outflow tract on the lateral view. Dilation of the pulmonary arteries may also occur in the presence of large pulmonary emboli, and this finding provides additional physiologic information concerning RV function.⁴¹ It is important to remember that the pulmonic valve lies more superiorly in the outflow tract and more anteriorly than does the aortic valve (see **Fig. 15-4**).

Aortic Valve and Aorta

The most commonly seen abnormality of the aorta is dilation, and the way that the aorta dilates is a function of the underlying pathology (**see Chapter 57**). It is often possible to define the pathology by a combination of the pattern of dilation and associated cardiac abnormalities.²² On the frontal CXR, aortic dilation appears as a prominence to the right of the middle mediastinum (**Fig. 15-12**). There is also a prominence in the anterior mediastinum on the lateral view, posterior to the pulmonary outflow tract (**Fig. 15-13**; see also **Figs. 15-6** and **e15-2**). Dilation of the aortic root is seen with aortic valve disease (both stenosis and regurgitation) but more frequently has other causes, such as long-term, poorly controlled systemic hypertension or generalized atherosclerosis with ectasia.

In aortic valve stenosis (**see Chapter 63**), there is usually focal dilation of the aortic root, often subtle and frequently without LV enlargement (see **Fig. 15-13**). It is important to look for this because often no other signs are apparent on the CXR, even in the presence of a very small valve area. The left ventricle generally hypertrophies in response to increased afterload rather than dilating as it does in response to the increased volume that occurs with aortic regurgitation. LV hypertrophy is visualized with echocardiography, CT, or CMR, but the ventricle may appear entirely normal on the CXR despite tight aortic stenosis. Aortic valve calcification is pathognomonic for significant aortic valve disease (see **Figs. 15-13** and **e15-10**), but it is usually difficult to see on a CXR because of the overlying soft tissue densities and the minimal blurring caused by cardiac motion. If calcification is present, it is much more easily seen with fluoroscopy (as during cardiac catheterization) or CT (see **Fig. 18-25**). Despite the decreased resolution of fluoroscopy in comparison to a standard CXR, real-time visualization facilitates definition of calcification because it eliminates blurring caused by motion.^{38,39} Calcification of the aorta beyond the valve may also have clinical significance.^{34,39,40} In the subset of patients with aortic stenosis and LV decompensation, there is LV and aortic root dilation. The presence or absence of aortic valve calcification may help in the differentiation.

Aortic involvement is generally more diffuse in aortic regurgitation than in aortic stenosis and is more easily seen (**see Chapter 63**). In pure aortic regurgitation, the left atrium is not typically enlarged. Over time, however, dilation of the mitral annulus may occur secondary to LV dilation, with resultant mitral regurgitation and LA dilation. Although aortic regurgitation most often

FIGURE e15-10 Mitral annulus calcification on PA (**A**) and lateral (**B**) projections. This calcification (*black arrowheads*) lies below a line drawn from the left main bronchus to the anterior costophrenic sulcus, which localizes it to the mitral valve. The calcified aortic valve in this patient lies more anteriorly and above this line (*white arrowhead*).

FIGURE 15-13 Chest radiographs of a 65-year-old woman with severe aortic stenosis. **A**, Frontal view showing a prominent aortic root to the right of midline (arrowheads). Note the absence of cardiomegaly and the presence of a normal pulmonary vascular pattern. **B**, Lateral view demonstrating calcification of the aortic valve leaflets (arrows). There is a prominent, mildly dilated aortic root (arrowheads).

occurs as a result of congenital defects, degenerative valve disease, or rheumatic heart disease (with associated mitral valve disease), it may also be caused by diseases of the aortic root, including cystic medial necrosis, with or without Marfan syndrome. In cystic medial necrosis the involvement is diffuse and there is generally dilation of the aorta from the level of the valve at least through the arch, with a gradual transition to normal diameter (see Chapter 57). Aortic regurgitation may be caused by dilation of the valve or by aortic dissection into the valve ring. In tertiary syphilis, now rarely seen, the characteristic finding is marked dilation of the aorta from the root to the arch, with an abrupt return to normal diameter at this level. Other aortic abnormalities, such as acute or chronic dissection and traumatic rupture or pseudoaneurysm, generally require cross-sectional imaging for clear delineation. In the setting of suspected acute trauma to the chest or mediastinum, obtaining a CXR may unnecessarily delay appropriate diagnosis and intervention, as in the case of suspected aortic rupture. The findings on a CXR are generally nonspecific and indirect, such as mediastinal widening, blood at the left apex, a large left pleural effusion (presumably blood), deviation of the trachea to the right, or rib fractures. Multislice CT can provide a more rapid and accurate answer (see Chapter 18).

Pleura and Pericardium

The pleura and pericardium also require systematic evaluation. The pericardium is rarely distinctly definable on a CXR.⁴² In two situations, however, it can be seen: calcification or, occasionally, in the presence of a large effusion. With a large pericardial effusion, the visceral and parietal pericardial layers separate. Because a fat pad is associated with each, it is sometimes possible to make out two parallel lucent lines (i.e., fat) on the lateral CXR, usually in the area of the cardiac apex, with density (fluid) between them. CMR, echocardiography, and CT, however, are all far more reliable in defining a pericardial effusion (see Chapter 71). Nonetheless, if the cardiac silhouette is enlarged on the CXR, it is important to look for specific explanations. Although LV dilation and valvular disease are more common causes, the presence of an unsuspected effusion is worth considering. Typically, the cardiac silhouette has a water bottle shape in the presence of a pericardial effusion, but this shape is not in itself diagnostic.

Pleural and pericardial calcification can occur but are often not obvious (see Fig. 15-7; see also Fig. 71-11). Pericardial calcification is associated with a history of pericarditis, with multiple possible causes; tuberculosis and various viruses are the most common. Pericardial calcification is usually thin and linear and follows the contour of the pericardium, and it is often seen only on one view, as in Figure 15-7.

Myocardial calcification secondary to a large MI with transmural necrosis is rare and tends to be thicker, more focal, and less consistent with the outer contour of the heart. Pleural calcification is easily distinguishable from pericardial calcification and is essentially pathognomonic for asbestos exposure. It is associated with a high risk for malignant mesothelioma but is not diagnostic of this type of tumor.

Additional Specific Considerations

A catalog of all the CXR findings associated with cardiac disease is beyond the scope of this chapter, but several additional specific entities and situations are worth considering either because they are common or because they are characteristic of certain disease states. The most common explanation for cardiomegaly and pulmonary vascular redistribution is ischemic heart disease.²⁶⁻³⁰ In most patients with acute MI, the cardiac silhouette is not enlarged but there is pulmonary vascular redistribution, consistent with an acute

increase in LVEDP. This condition is most easily defined when the CXR is compared with a previous or subsequent one. After a transmural MI, a variety of alterations can occur. LV aneurysms, either true (generally in the distribution of the left anterior descending artery; see Fig. e15-5) or false (i.e., pseudoaneurysms, usually involving the base or posterior wall), are uncommon.⁴³ Although their locations differ, their appearances are similar; there is focal prominence of the anterolateral cardiac contour with true aneurysms, there may be linear myocardial calcification, and the cardiac margin is unusually sharp because the area of the aneurysm does not have normal cardiac motion. Again, this is best seen in comparison to previous CXRs.

It is impossible to define a postinfarction ventricular septal defect on the CXR because the findings are nonspecific cardiac dilation and evidence of LV or biventricular failure. After percutaneous repair, however, the septal repair device can often be identified.^{44,45}

IMPLANTABLE DEVICES AND OTHER POSTSURGICAL FINDINGS

A final important and broad area concerns the CXR following surgery or other percutaneous interventions in and around the heart,⁴⁴⁻⁴⁹ including prosthetic valves (placed either surgically or percutaneously), pacemakers and ICDs (Fig. 15-14), intra-aortic counterpulsation balloons (see Fig. 15-9), and ventricular assist devices. Clear changes also occur after surgery, such as the presence of clips on the side branches of the saphenous veins used for coronary artery bypass grafting (see Fig. e15-5), as well as retrosternal blurring and effusions (see Fig. 15-2). Some of these findings may be temporary, such as the lines and tubes associated with surgery and effusions. Pacemakers and ICDs present specific questions (see Chapter 36).^{46,47} The first is whether the leads are intact and the second is the position of the tips (see Fig. 15-14). Although course and tip position are generally confirmed fluoroscopically at the time of placement, malposition can occur. If there are two leads, the tips should generally be in the anterolateral wall of the right atrium and the apex of the right ventricle. If the leads are not positioned in this way, the reasons should be carefully determined. That is, are they malpositioned because of error or anatomic variants (e.g., a persistent left SVC that empties into the coronary sinus and then the right atrium; Fig. e15-11)⁴⁹ or because the lead belongs in the coronary sinus (Fig. e15-12)? Additionally, the position of the wires and valve prostheses can help in the definition of specific chamber enlargement (Fig. e15-13; see also Fig. 15-14).

CONCLUSION

CXRs provide a wealth of physiologic and anatomic information. Accordingly, they play a central role in the evaluation and management of patients with a wide variety of cardiovascular and other

FIGURE e15-11 Chest radiographs of a 62-year-old woman with two pacemakers—the left-sided pacemaker implanted because of failure of the right. As seen on the frontal (**A**) and lateral (**B**) views, the right-sided wire traverses the right SVC and right atrium, and its tip lies superiorly and anteriorly in the pulmonary outflow tract. The left-sided wire traverses a persistent left SVC (a normal anatomic variant), and the coronary sinus and its tip, the lower of the two, is in the right atrium.

FIGURE e15-12 A, B, Chest radiographs of a 78-year-old man after aortic valve replacement. Note the position of the wire (*small arrow*) through the coronary sinus into the great coronary vein (running parallel to the left anterior descending coronary artery) and biventricular enlargement. Also note the position of the separate ICD tip in the RV apex (*large arrow*).

FIGURE e15-13 Chest radiographs of a 28-year-old man who has undergone aortic valve replacement with a porcine bioprosthesis. **A**, PA view. There is marked LV enlargement with a downwardly displaced apex. Note the pacemaker wire with its tip in the RV apex. **B**, The lateral view confirms primary LV dilation and shows the position of the aortic valve, as well as the tip of the pacing wire in the RV apex. This confirms LV versus RV dilation.

FIGURE 15-14 Radiographs of an older man with heart failure, biventricular dilation, a large hiatal hernia (arrows; note the air-fluid level), and pacemaker leads in the right atrium and right ventricle.

disorders. The radiation dose inherent in obtaining radiographs should always be considered. Portable CXRs should be used as infrequently as possible because the information that they provide is limited and may even be misleading (e.g., in defining cardiomegaly or in ruling out a pneumothorax or effusion). Standard 6-foot frontal and lateral CXRs, on the other hand, are almost always clinically useful. Whether recorded conventionally or digitally, if they are evaluated carefully by using a systematic approach and, whenever possible, compared with previous CXRs, it is hard to overstate their importance.

APPROPRIATE USE CRITERIA, 316

The era of noninvasive radionuclide cardiac imaging in humans began in the early 1970s with the first reports of noninvasive evaluation of myocardial blood flow at rest. Since that time, major advances have been achieved in the technical ability to image cardiac physiology and pathophysiology, including that of myocardial blood flow, myocardial metabolism, and ventricular function. Just as important has been a major growth in the understanding of how to apply the image information to care of patients and the effect of that information on clinical decision making. Ultimately, the role of information derived from any imaging procedure is to enhance the clinician's decision-making process for amelioration of symptoms or improvement of clinical outcomes or both.

TECHNICAL ASPECTS OF IMAGE ACQUISITION, DISPLAY, AND INTERPRETATION

Single Photon Emission Computed Tomography Imaging of Perfusion and Function

The most commonly performed imaging procedure in nuclear cardiology is single photon emission computed tomography (SPECT) myocardial perfusion imaging (MPI). After injection of the chosen radiotracer, the isotope is extracted from the blood by viable myocytes and retained within the myocyte for some time. Photons are emitted from the myocardium in proportion to the magnitude of tracer uptake, in turn related to perfusion. The standard camera used in nuclear cardiology studies, a gamma camera, captures the gamma ray photons and converts the information into digital data representing the magnitude of uptake and the location of the emission. The photoemissions collide along their flight path with a detector crystal. There, the gamma photons are absorbed and converted into visible light events (a scintillation event). Emitted gamma rays are selected for capture and quantitation by a collimator attached to the face of the camera detector system. Most often, parallel-hole collimators are

used so that only photon emissions coursing perpendicular to the camera head and parallel to the collimation holes are accepted (Fig. 16-1). This arrangement allows appropriate localization of the source of the emitted gamma rays. Photomultiplier tubes, the final major component in the gamma camera, sense the light scintillation events and convert the events into an electrical signal to be further processed (see Fig. 16-1). The final result of SPECT imaging is the creation of multiple tomograms, or slices, of the organ of interest, composing a digital display representing radiotracer distribution throughout the organ.¹ With SPECT MPI, the display represents the distribution of perfusion throughout the myocardium.

SPECT Image Acquisition. To construct the three-dimensional model of the heart from which tomograms are created, the myocardial perfusion data must be sampled from multiple angles over 180 or 360 degrees around the patient. Multiple images, each comprising 20 to 25 seconds of emission data, are collected. Each of the separate "projection" images constitutes a two-dimensional snapshot of myocardial perfusion from the angle at which the projection was acquired. Then the imaging information from each of the angles is back-projected onto an imaging matrix, creating a reconstruction of the organ of interest. Detailed reviews are available for more extensive information on the technical aspects of SPECT imaging and image reconstruction.¹

SPECT Image Display. From the three-dimensional reconstruction of the heart, computer processing techniques are used to identify the long axis of the left ventricle, and standardized tomographic images in three standard planes are derived. *Short-axis images*, representing donut-like slices of the heart cut perpendicular to the long axis of the heart, are displayed beginning from the apex and moving toward the base. This tomographic orientation is similar to the short-axis view in two-dimensional echocardiography (see Chapter 14), although it is shifted counterclockwise (Fig. 16-2A). Tomographic slices cut parallel to the long axis of the heart and also parallel to the long axis of the body are termed *vertical long-axis tomograms* (Fig. 16-2B), and slices also cut parallel to the long axis of the heart but perpendicular to the vertical long-axis slices are known as *horizontal long-axis tomograms* (Fig. 16-2C). From all of these tomographic planes, the entire three-dimensional myocardium is sampled and displayed, minimizing overlap of structures.

FIGURE 16-1 Capture of emitted photons by a gamma camera. Emissions are captured by a parallel-hole collimator, allowing photons to interact with a detector crystal, and are recorded as scintillation events. The event is localized on the basis of where the photon interacts with the crystal.

Basics of Quality Control. The quality of SPECT MPI and the “accuracy” of the representation of regional myocardial perfusion depend on multiple quality control issues. These issues include the stability of the tracer distribution in the organ of interest during the acquisition interval, the absence of motion of the patient or organ of interest or both during the acquisition, and the absence of overlying structures that would attenuate the photon emissions from one region relative to another region across the different projection images. The foregoing issues are related to the patient and the organ being imaged; other quality control issues involve the camera and detector system, including the uniformity of photon detection efficiency across the camera face as well as the stability of the camera across the entire orbit of acquisition.²

It is important in interpreting SPECT images to be aware of possible sources of image artifacts. Discrete motion of the patient (with consequent motion of the heart outside its original field) causes an abnormality in the final images that may be corrected with motion correction software. Imaging artifacts commonly occur because of the effects of overlying structures that attenuate photon emissions. These artifacts include breast attenuation in women and attenuation of the inferobasal wall related to the diaphragm, most commonly seen in men. Strategies to overcome quality-specific problems such as attenuation are described subsequently.

New Technology: High-Speed SPECT Imaging

High-speed SPECT technology introduces a new design of SPECT in terms of both photon acquisition and reconstruction algorithms. Standard SPECT imaging with collimators using a parallel-hole design is inherently inefficient, as only a relatively small proportion of the camera and collimator surface area is used to capture photons emitted from the heart. Advances in camera and collimator technology have substantially increased the efficiency of count capture, by design features that allow much of the available detector area to image the cardiac field of view, increasing count sensitivity manyfold. One approach uses a series of small, pixilated solid-state detector columns with cadmium zinc telluride or cesium iodide : thallium crystals, which provide considerably more information for each detected gamma ray. In addition, the design of the solid-state detector with wide-angle tungsten collimators combined with a novel image reconstruction algorithm provides true three-dimensional, patient-specific images localized to the heart.³ Compared with the conventional SPECT cameras, the high-speed SPECT systems can provide up to eightfold increase in count rates, thereby reducing imaging times significantly from 14 to 15 minutes with a conventional Anger camera to 5 to 6 minutes with the newer solid-state cameras while achieving a twofold increase in spatial resolution from 9 to 11 mm for Anger cameras to 4.3 to 4.9 mm for cadmium zinc telluride cameras.

In addition to advances in camera technology, software driving image reconstruction has also evolved. One technique, known as

resolution recovery, improves spatial resolution while at the same time reducing noise in the images. Thus studies acquired over a much shorter period of time when reconstructed using these techniques can yield images with the same signal-to-noise ratio as those acquired and reconstructed with standard techniques and timing.⁴ Reduced imaging times should translate to improved patient comfort and satisfaction as well as less motion and fewer motion artifacts. An additional advantage of high-speed SPECT imaging is the potential for administration of lower doses of radiopharmaceuticals without sacrificing image resolution and quality, thereby reducing radiation dose to patients. The reduced imaging time in concert with reduced radiopharmaceutical doses may be cost-effective, with implications for future appropriateness of SPECT imaging.⁵

SPECT Perfusion Tracers and Protocols

Thallium-201

Thallium-201 (^{201}Tl) was introduced in the 1970s and propelled the clinical application of MPI as an adjunct to exercise treadmill testing. ^{201}Tl is a monovalent cation with biologic properties similar to those of potassium. Because potassium is the major intracellular cation in muscle and is virtually absent in scar tissue, ^{201}Tl is a well-suited radionuclide for differentiation of normal and ischemic myocardium from scarred myocardium.⁶ ^{201}Tl emits 80 keV of photon energy and has a physical half-life of 73 hours. The initial myocardial uptake early after intravenous injection of thallium is proportional to regional blood flow. First-pass extraction fraction (the proportion of tracer extracted from the blood as it passes through the myocardium) is high, in the range of 85%. It is transported across the myocyte cell membrane by the Na^+, K^+ -adenosine triphosphatase (ATPase) transport system and by facilitative diffusion. Peak myocardial concentration of thallium is achieved within 5 minutes of injection, with rapid clearance from the intravascular compartment. Although the initial uptake and distribution of thallium are primarily a function of blood flow, the subsequent redistribution of thallium, which begins within 10 to 15 minutes after injection, is unrelated to flow but is related to the rate of its clearance from myocardium, linked to the concentration gradient between myocyte levels and blood levels of thallium (Fig. 16-3A). Thallium clearance is more rapid from normal myocardium with high thallium activity than from myocardium with reduced thallium activity (ischemic myocardium), a process termed *differential washout* (Fig. 16-3B).

Thallium studies can be divided into protocols in which ^{201}Tl is administered during stress and those in which it is given with the subject at rest.⁶ After stress, the reversal of a thallium defect from the initial peak stress to delayed 3- to 4-hour or 24-hour redistribution images is a marker of reversibly ischemic, viable myocardium. When thallium is injected in the resting state, the extent of thallium defect reversibility from the initial rest images to delayed redistribution images (at 3 to 4 hours) reflects viable myocardium with hypoperfusion at rest. When scarred myocardium is present, the initial rest or stress thallium defect persists over time; such deficits are termed *irreversible* or *fixed defects*. However, in some patients with coronary artery disease (CAD), the initial uptake of thallium during stress may be severely decreased, and tracer accumulation from the recirculating thallium in the blood during the redistribution phase may be slow or even absent because of rapid decline of thallium levels in the blood. The result is that some severely ischemic but viable regions may show no redistribution on either early (3- to 4-hour) or late (24-hour) imaging, even if viable myocardium is present. Viable myocardium in this situation can be revealed by raising blood levels of thallium by reinjection of a small dose (1 to 2 mCi) of thallium at rest. Thus, in some patients, thallium reinjection is necessary to identify viable myocardium when there are irreversible defects on stress-redistribution images.

Technetium 99m-Labeled Tracers

Technetium 99m ($^{99\text{m}}\text{Tc}$)-labeled myocardial perfusion tracers were introduced in the clinical arena in the 1990s.⁶ $^{99\text{m}}\text{Tc}$ emits 140 keV of photon energy and has a physical half-life of 6 hours. Despite the excellent myocardial extraction and flow kinetic properties of ^{201}Tl ,

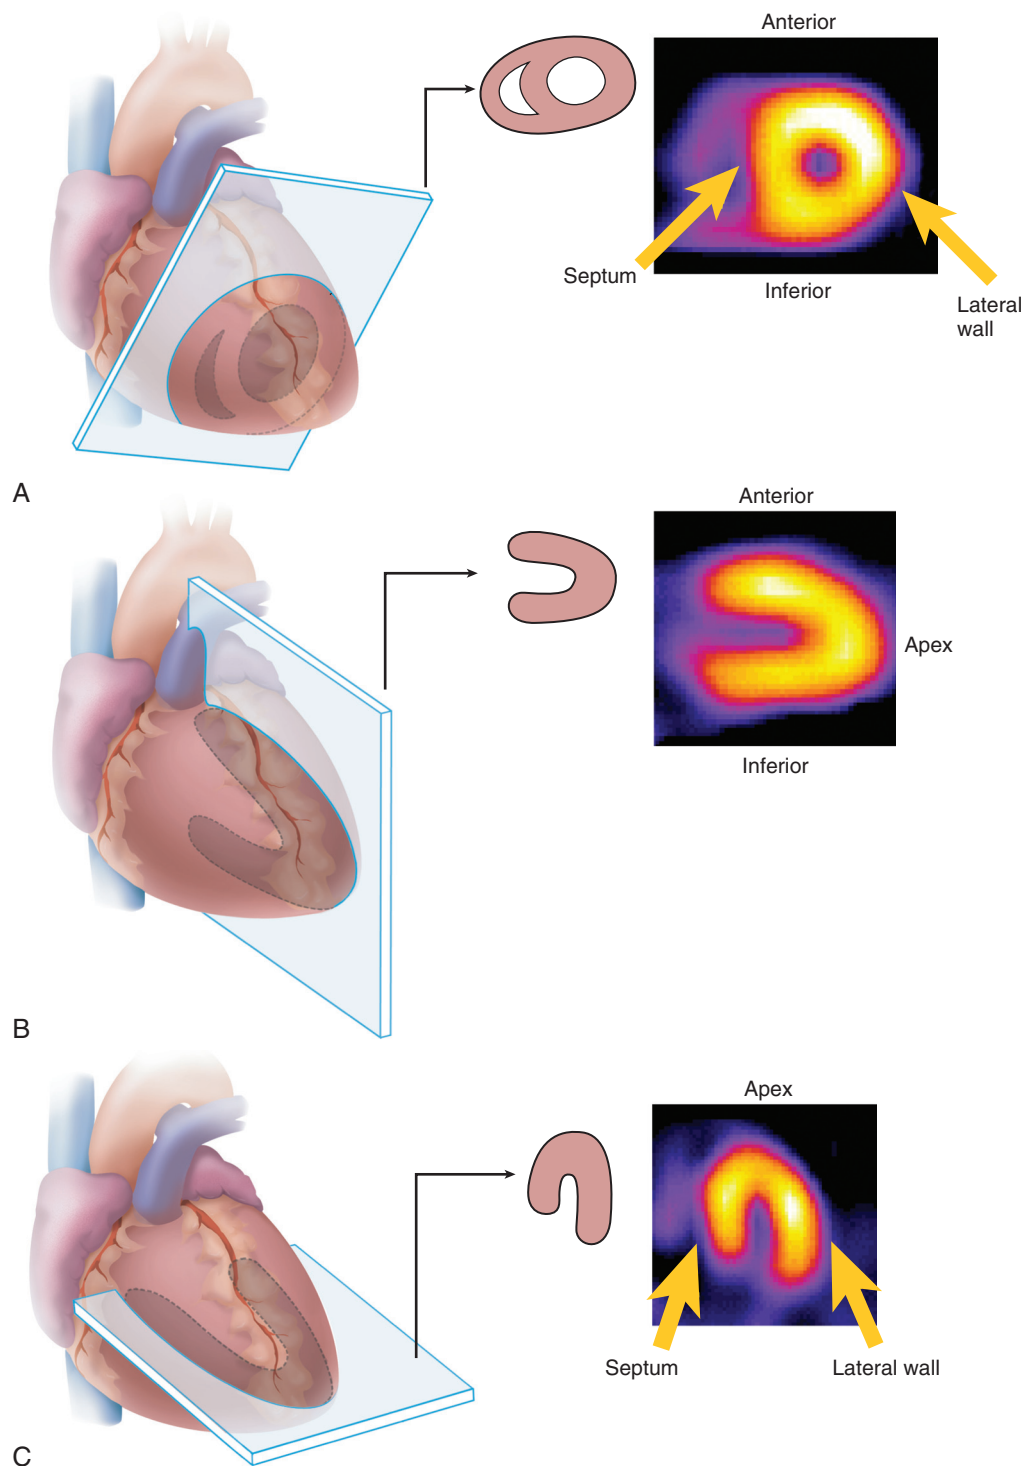

FIGURE 16-2 Standard SPECT imaging display. **A**, The short-axis images represent a portion of the anterior, lateral, inferior, and septal walls. **B**, Vertical long-axis images represent the anterior wall, apex, and inferior wall. **C**, Horizontal long-axis images represent the septum, apex, and lateral walls.

its energy spectrum of 80 keV is suboptimal for conventional gamma cameras (ideal photopeak in the 140-keV range). In addition, the long physical half-life of ^{201}Tl (73 hours) limits the amount of ^{201}Tl that may be administered to stay within acceptable radiation exposure parameters. Thus $^{99\text{m}}\text{Tc}$ -labeled tracers improve on these two limitations of ^{201}Tl . Although three $^{99\text{m}}\text{Tc}$ -labeled tracers—sestamibi, tetrofosmin, and tetrofosmin—have received U.S. Food and Drug Administration (FDA) approval for detection of CAD, only sestamibi and tetrofosmin are available for clinical use at present.

Sestamibi and tetrofosmin are lipid-soluble cationic compounds with first-pass extraction fraction in the range of 60%. Myocardial uptake and clearance kinetics of both tracers are similar. They cross sarcolemmal and mitochondrial membranes of myocytes by passive distribution, driven by the transmembrane electrochemical gradient, and they are retained within the mitochondria.⁶ Redistribution of these tracers is minimal compared with that for thallium. Consequently, myocardial perfusion studies with $^{99\text{m}}\text{Tc}$ -labeled tracers require two separate injections, one at peak stress and the second at rest.

FIGURE 16-3 ^{201}Tl redistribution. **A**, After initial uptake into the myocyte, an equilibrium is created between the intracellular and extracellular concentrations of thallium. After blood levels diminish during the redistribution phase, the equilibrium favors egress of thallium out of the myocyte. **B**, On the basis of that equilibrium, thallium concentration diminishes over time in zones of normal uptake while diminishing more slowly in zones with less initial thallium uptake, that is, those with diminished flow reserve or ischemia. In this example, segment 1 of the myocardial schematic is supplied by an artery with an 80% stenosis and segment 2 is supplied by a normal artery. During peak stress, normal blood flow reserve is present in segment 2; blunted flow reserve, based on the presence of stenosis, is present in segment 1, and there is less initial thallium uptake into segment 1 (time point A). Thallium washout is more rapid from the territory with initially normal uptake and slower from the ischemic zone, creating the phenomenon of differential washout. When redistribution imaging is done 3 to 4 hours later (time point B), thallium concentrations are equal in segments 1 and 2. Thus a reversible stress defect is seen in segment 1, based on the redistribution properties and differential washout. (Modified from Dilsizian V: *SPECT and PET techniques*. In Dilsizian V, Narula J [eds]: *Atlas of Nuclear Cardiology*. Braunwald E [series ed]. Philadelphia, Current Medicine, 2003, pp 19-46.)

Three basic protocols⁷ with $^{99\text{m}}\text{Tc}$ -labeled tracers have been used: (1) a single-day study, in which myocardial blood flow is interrogated at rest and at peak stress, or in the reverse order, as long as the first injected dose is low (8 to 12 mCi) and the second injected dose is high (24 to 36 mCi); (2) a 2-day study (commonly performed in patients with large body habitus), in which higher doses of the tracer are injected (24 to 36 mCi) both at rest and at peak stress to optimize

myocardial count rate; and (3) a dual-isotope technique, in which injection of ^{201}Tl at rest is followed by injection of a $^{99\text{m}}\text{Tc}$ tracer at peak stress. The last approach takes advantage of the favorable properties of each of the two tracers, including the high-quality gated SPECT images obtained with $^{99\text{m}}\text{Tc}$ and the potential to acquire redistribution images with ^{201}Tl (either at 4 hours before the stress study or at 24 hours after the $^{99\text{m}}\text{Tc}$ activity has decayed). A comparison of the properties of the available isotopes for perfusion imaging is presented in [Table 16-1](#).

SPECT Image Interpretation and Reporting. SPECT myocardial perfusion images may be evaluated visually. The interpreter describes the perfusion pattern findings on stress and then visually interprets whether defects observed on the stress images are or are not reversible. Because the imaging data are digital, computer-aided quantitative analysis also may be used. Validated software programs for semiquantitative or fully automated quantitative analysis of SPECT myocardial perfusion images are now widely available.

General Principles of Interpretation and Reporting. For any type of image interpretation, visual or quantitative, the key elements to be reported include the presence and location of perfusion defects and whether defects on stress images are reversible on the rest images (implying stress-induced ischemia) or whether stress perfusion defects are irreversible or fixed (often implying myocardial infarction [MI]). Moreover, substantial literature has documented that the extent and the severity of the perfusion abnormality are independently associated with clinical outcomes (risk of adverse events over time) and thus contribute importantly to the information on risk stratification to be conveyed to the ordering clinician.⁸ The extent of perfusion abnormality refers to the amount of myocardium or vascular territory that is abnormal, and the severity refers to the magnitude of reduction in tracer uptake in abnormal zone relative to normal. Examples of stress and rest SPECT myocardial perfusion abnormalities of varying extents and severities are shown in [Figures 16-4 to 16-6](#). These concepts imply that it is not sufficient to describe a stress perfusion imaging test as simply “abnormal.” Rather, a clinically relevant interpretation will include a description of the magnitude of abnormality as well as the extent of ischemia, extent of infarct, and localization to specific myocardial regions or vascular territories. The final report will incorporate all of the clinical data, the stress testing result, and the imaging data to provide comprehensive information to the referring clinician, in a timely and clinically meaningful way.

To minimize subjectivity in image interpretation, semiquantitative visual analysis or fully quantitative computer analysis may be applied to MPI data.⁷ With semiquantitative visual analysis, a score is assigned to represent perfusion for each of multiple segments of the myocardium. A segmentation model has been standardized for this approach by dividing the myocardium into 17 segments⁹ on the basis of three short-axis slices and a representative long-axis slice to depict the apex ([Fig. 16-7](#)). Perfusion is graded within each segment on a scale of 0 to 4, with 0 representing normal perfusion and 4 representing a very severe perfusion defect. Scores for all 17 segments are added to create a “summed” score. The sum of the segmental scores from the stress images—the *summed stress score* (SSS)—represents the extent and severity of stress perfusion abnormality, the magnitude of perfusion defects related to both ischemia and infarction. The sum of the 17 segmental scores from the rest images (the *summed rest score*, SRS) represents the extent of infarction. The *summed difference score* (SDS) is derived by subtracting the SRS from the SSS and represents the extent and severity of stress-induced ischemia. The segmental scores can be assigned subjectively by the image interpreter or automatically by widely available software programs. As discussed subsequently, a substantial literature has validated these summed scores, particularly the SSS, as predictors of natural history outcomes.

Because SPECT MPI data are a digital representation of radiotracer distribution, the data can also be analyzed quantitatively. The most common technique involves creation of a circumferential profile of relative tracer activity around the tomogram of interest, such as a short-axis tomogram. With this technique, each short-axis tomogram is sampled at every 3 to 6 degrees for 360 degrees, along a ray extending from the center of the image ([Fig. e16-1](#)). The maximum counts at a picture element (pixel) along the ray, usually occurring in the mid-portion of the myocardium, are recorded for each angle. The data may be plotted to create a profile of the perfusion pattern of that tomogram relative to the most “normal” area of uptake, which is assigned a value of 100% uptake (see [Fig. e16-1](#)). Circumferential

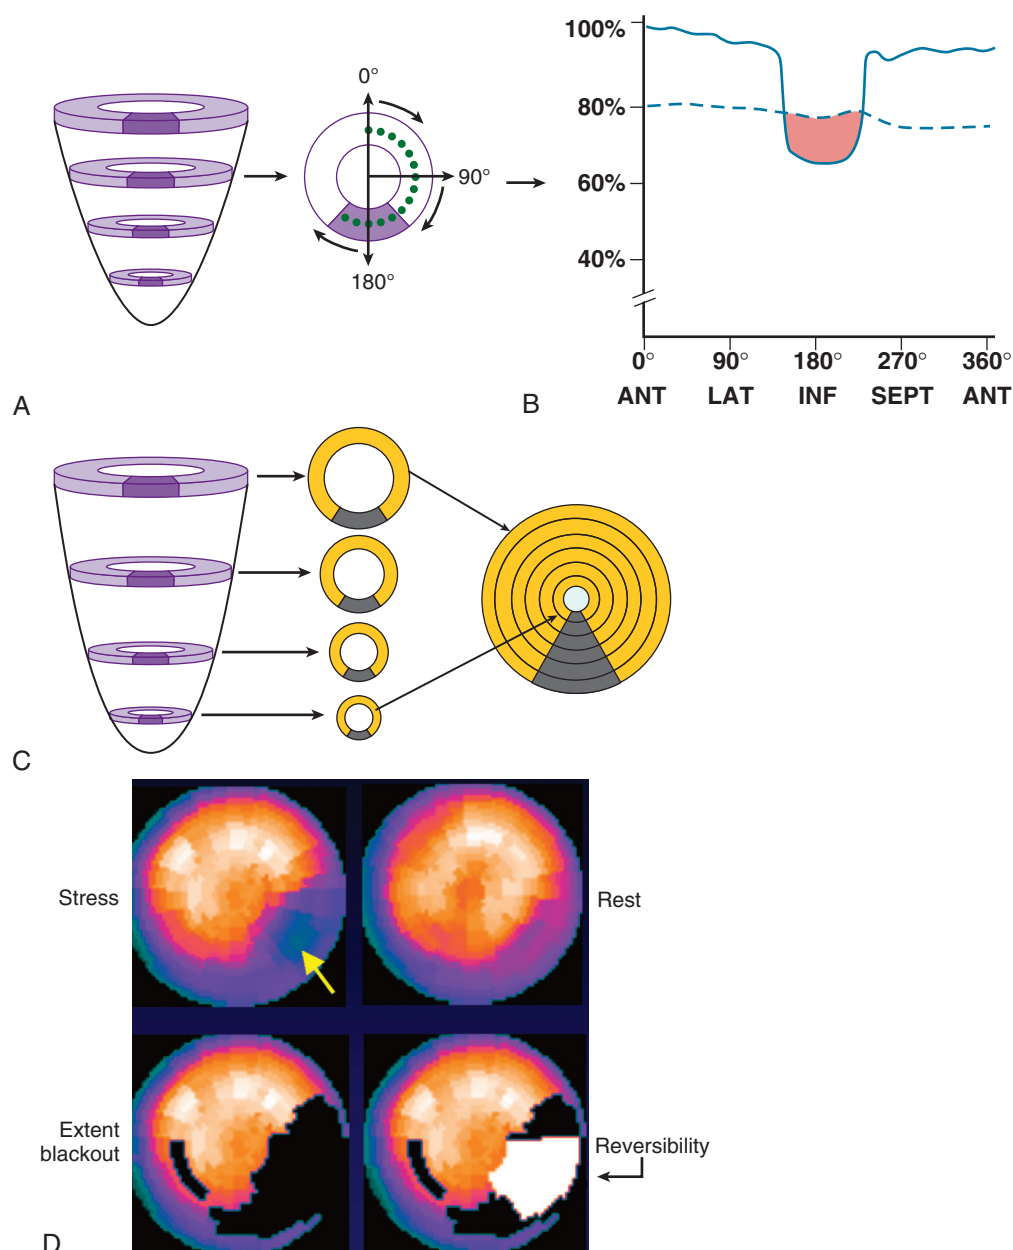

FIGURE e16-1 Quantitative analysis of SPECT imaging. **A**, Circumferential profile analysis of tracer uptake along rays emanating from the center of the short-axis tomogram. From this procedure, a circumferential profile of tracer uptake around the myocardium is developed for each short-axis tomogram. In this example, there is a perfusion defect in the inferior wall (darker purple area). **B**, The data are plotted relative to location around the myocardium (x axis) and “normalized” to the point of peak uptake, which is assigned a value of 100% (y axis). The patient’s data (solid line) are compared with lower limits of normal (dashed line) derived from a group of subjects without CAD of the same gender. From this comparison, the quantitative extent and severity of the perfusion abnormality can be derived (red area). ANT = anterior; INF = inferior; LAT = lateral; SEPT = septal. **C**, Data from all of the individual short-axis tomograms can be combined to create a bull’s-eye polar plot, representing a two-dimensional compilation of all of the three-dimensional short-axis perfusion data. The extent of the inferior wall perfusion defect (gray area on individual profiles and polar plot) is seen on the two-dimensional map. **D**, A bull’s-eye polar plot for a patient with a reversible defect of the inferolateral wall (yellow arrow on the stress bull’s-eye plot, upper left). The blackout area (on the extent blackout plot, lower left) represents the myocardium that falls below the lower limits of normal; in the reversibility plot (lower right), the white area represents the extent of that abnormality that is reversible (ischemic) on rest imaging. (Images courtesy Ernest García, PhD.)

TABLE 16-1 Properties of SPECT Tracers

TRACER	PHYSICAL HALF-LIFE	UPTAKE	MYOCARDIAL CLEARANCE	DIFFERENTIAL WASHOUT	MAXIMUM EXTRACTION
^{201}Tl	73 hours	Active	~50% at 6 hours	Yes	~0.70
$^{99\text{m}}\text{Tc}$ -sestamibi	6 hours	Passive	Minimal	Minimal	0.39
$^{99\text{m}}\text{Tc}$ -tetrafosmin	6 hours	Passive	Minimal	Minimal	0.24
$^{99\text{m}}\text{Tc}$ -teboroxime	6 hours	Passive	~50% at 10 minutes	Yes	0.72

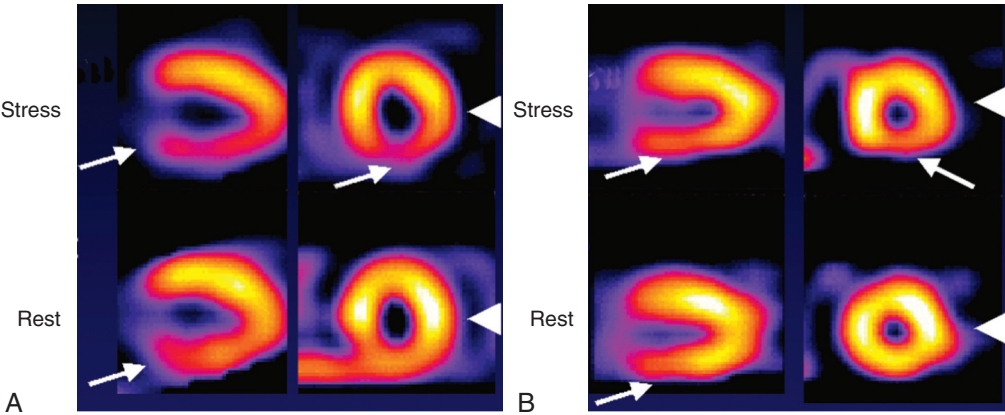

FIGURE 16-4 SPECT images of inferior wall abnormalities of differing extent and severity. **A**, A large, moderately severe, reversible inferior wall defect (arrows) reflecting a moderately severe flow reserve abnormality. **B**, A milder, reversible inferior wall defect (arrows) reflecting either a less severe stenosis or a severe stenosis with well-developed collaterals minimizing the defect severity. In both patients, a mild lateral wall reversible defect also is present (arrowheads). Note how the lateral wall brightens relative to the septum on the rest images compared with the stress images.

FIGURE 16-5 Examples of single vascular territory reversible defects. **A**, A reversible inferior wall defect (arrows) in the short-axis (SA) and vertical long-axis (VLA) views, consistent with inducible ischemia in the right coronary artery territory. **B**, A reversible lateral wall defect (arrows) in the SA and horizontal long-axis (HLA) views (arrowheads), consistent with inducible ischemia in the left circumflex coronary artery territory. **C**, A reversible anterior wall defect (arrows) in the SA and VLA views, consistent with inducible ischemia in the left anterior descending (LAD) artery territory. **D**, Fixed perfusion pattern consistent with LAD artery territory infarct. There are fixed defects involving the apex in the HLA view (arrowheads), and the anteroapical wall and apex in the VLA view (arrows). **E**, Fixed perfusion defect pattern involving the inferior wall (arrows) in SA view and in the VLA view (arrowheads), consistent with inferior infarct.

profiles for an individual patient can be compared directly with a composite profile representing normal perfusion. The normal perfusion data are created from studies performed in normal subjects with a very low clinical probability of CAD or in those with known normal coronary arteries. A quantitative extent of abnormality can be derived for each tomogram of the individual patient (the total amount of myocardium that falls below the lower limit of normal) as well as a derivation of the severity of the perfusion abnormality (the depth of the patient's perfusion abnormality relative to the lower limit of normal).

Most contemporary computer systems and analysis programs create bull's-eye or polar maps representing perfusion of the entire three-dimensional myocardium in a two-dimensional plot (Fig. 16-8; see also Fig. e16-1). Quantitative data may be derived on the extent of global perfusion abnormality, the abnormality within vascular territories, and the extent of reversible and fixed defects. These are often displayed as blackout maps, in which any pixel values falling below a set number of standard deviations below the normal limits is assigned

the color black, and the extent of that abnormality is expressed as a percentage of the presumed vascular territory and as a percentage of the left ventricle.

The American Society of Nuclear Cardiology (ASNC) has published guidelines outlining the elements of a comprehensive reporting structure.¹⁰

Advantages and Disadvantages of Visual and Quantitative Analysis. The accuracy of visual analysis is based on many factors, which include the experience and training of the reader as well as the quality of the imaging study. Well-trained readers will incorporate information from the raw data (such as the presence of apparent breast attenuation or an elevated diaphragm potentially attenuating the inferior wall) and adjust their threshold for interpreting an abnormality to optimize accuracy. Visual analysis is inherently subjective, however, and thus subject to variability, both between readers and within an individual reader. The quantitative programs and comparisons to normal data bases can perform with little or no human interaction. Thus the results are highly reproducible. This approach attempts

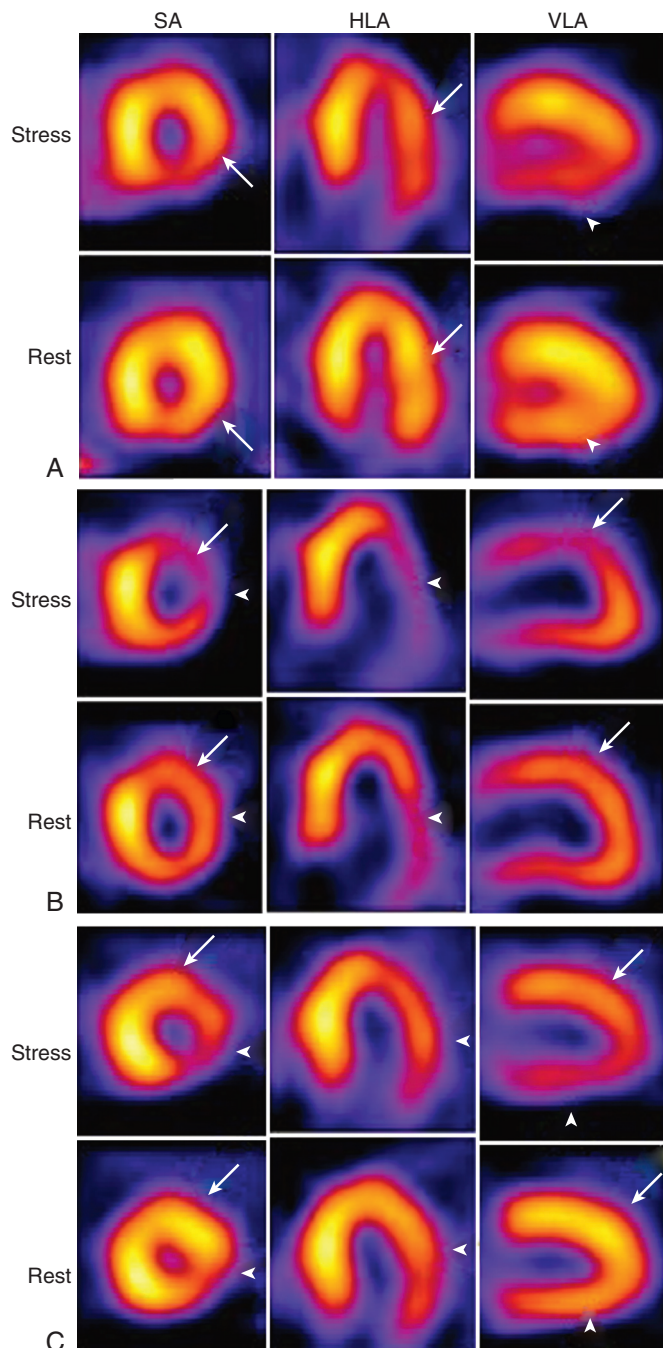

FIGURE 16-6 Examples of reversible defects in more than one vascular territory. **A**, A reversible lateral wall defect (arrows) in the short-axis (SA) and horizontal long-axis (HLA) views, consistent with inducible ischemia in left circumflex (LCx) coronary artery territory, and a reversible inferior wall defect (arrowheads) in the vertical long-axis (VLA) view, consistent with inducible ischemia in the right coronary artery (RCA) territory. **B**, A reversible anterior wall defect (arrows) in the SA and VLA views, consistent with inducible ischemia in the LAD artery territory, and a reversible lateral wall defect (arrowheads) in the SA and HLA views, consistent with inducible ischemia in LCx territory. **C**, Perfusion abnormalities in all three major vascular territories: a reversible anterior wall defect (arrows) in the SA and VLA views, consistent with inducible ischemia in the LAD territory; a reversible lateral wall defect (arrowheads) in the SA and HLA views, consistent with inducible ischemia in the LCx territory; and a reversible inferior wall defect (arrowheads) in the VLA view, consistent with inducible ischemia in the RCA territory.

to account for potential artifacts such as breast or diaphragm attenuation by the comparison of patient image data to image data from normal, gender-matched subjects (in which, for example, the lower limit of normal for the anterolateral wall of a woman would be lower than that of a man because of the presence of breast tissue). Nonetheless, artifacts that are not accounted for by the normal data

comparison, such as those introduced by motion or other suboptimal quality issues that the trained reader may recognize as probably artifactual, often may be called abnormal by quantitation. In practice, therefore, many readers will interpret MPI studies by visual analysis as well as by incorporating the quantitative data to arrive at a final conclusion. The more objective and reproducible nature of quantitative analysis is a strength with regard to its use in clinical trials that interrogate the effect of therapies on serial changes in myocardial perfusion.

Incorporating Bayesian Principles into Image Interpretation

Although it is possible to interpret MPI data in isolation and report only on what the images demonstrate, a more accepted interpretive methodologic principle is that the final interpretation should take into account the entirety of the data at hand. Hence the image data build on the already known clinical and stress test data, and the clinician should take all of this information into account when interpreting MPI data. An understanding of Bayesian probability principles is useful in this regard. Bayes theorem posits that the post-test probability of disease (or risk of an event after a test) is influenced not only by the sensitivity and specificity of the test but also importantly by the pretest probability of disease (see Chapter 13). This principle is illustrated in Figure 16-9. For a given positive test result, the post-test probability of disease may be distinctly lower in a patient with a very low pretest probability of disease compared with a different patient with a much higher pretest probability (Fig. 16-9A). In practice, MPI results are not simply positive or negative; rather, positive (i.e., abnormal) results can range from borderline-abnormal (uncertainty whether the abnormality may be an artifact or a mild perfusion defect) to strongly abnormal (i.e., extensive and severe defects, highly likely to be real and unlikely to represent artifact). Thus the “test positive” curve in Figure 16-9A can be thought of as a family of positivity curves, with distinct implications for post-test likelihood of disease (Fig. 16-9B).

The implication of incorporating these concepts for image interpretation can be illustrated by considering a mildly positive MPI study demonstrating a small mild reversible inferobasal defect. Although it is possible that this defect represents a small area of inferior inducible ischemia, it is also possible that the image may reflect diaphragm attenuation of the inferobasal wall predominantly affecting the stress image. The influence of the pretest probability data (i.e., pre-MPI) is illustrated in Figure 16-9C. For a young patient with nonanginal chest pain, the pretest probability of CAD is low. If the patient undergoes an exercise treadmill test (ETT) (see Chapter 13) as the stress portion of the MPI test and exercises to a good workload with no symptoms and no changes on the electrocardiogram (ECG), the post-ETT probability is even lower. The post-ETT probability then becomes the pre-MPI probability, as seen in Figure 16-9D. A positive test result, especially a mildly positive result, is still associated with a relative low post-test probability of CAD. A result reported as positive is more likely to represent a false-positive than a true-positive finding. By contrast, for an older patient being evaluated for anginal chest pain in whom ETT reproduces those symptoms and who exhibits positive ECG changes, the pre-MPI probability is very high, so the same MPI results are far more likely to represent a true-positive finding than a false-positive finding, as illustrated in Figure 16-9C and D. These examples illustrate how the clinical data may be incorporated into the MPI interpretation and also how Bayesian probability principles may be incorporated sequentially so that the image reader conveys information to the referring clinician that reflects the post-test probability of disease (and risk), rather than simply reporting what the image data show in isolation.

Important Signs in SPECT Imaging Analysis Beyond Myocardial Perfusion

Other abnormal findings provide additional information beyond that indicated by the perfusion pattern alone, including lung uptake of tracer (particularly ^{201}Tl) and transient ischemic dilation of the left ventricle.

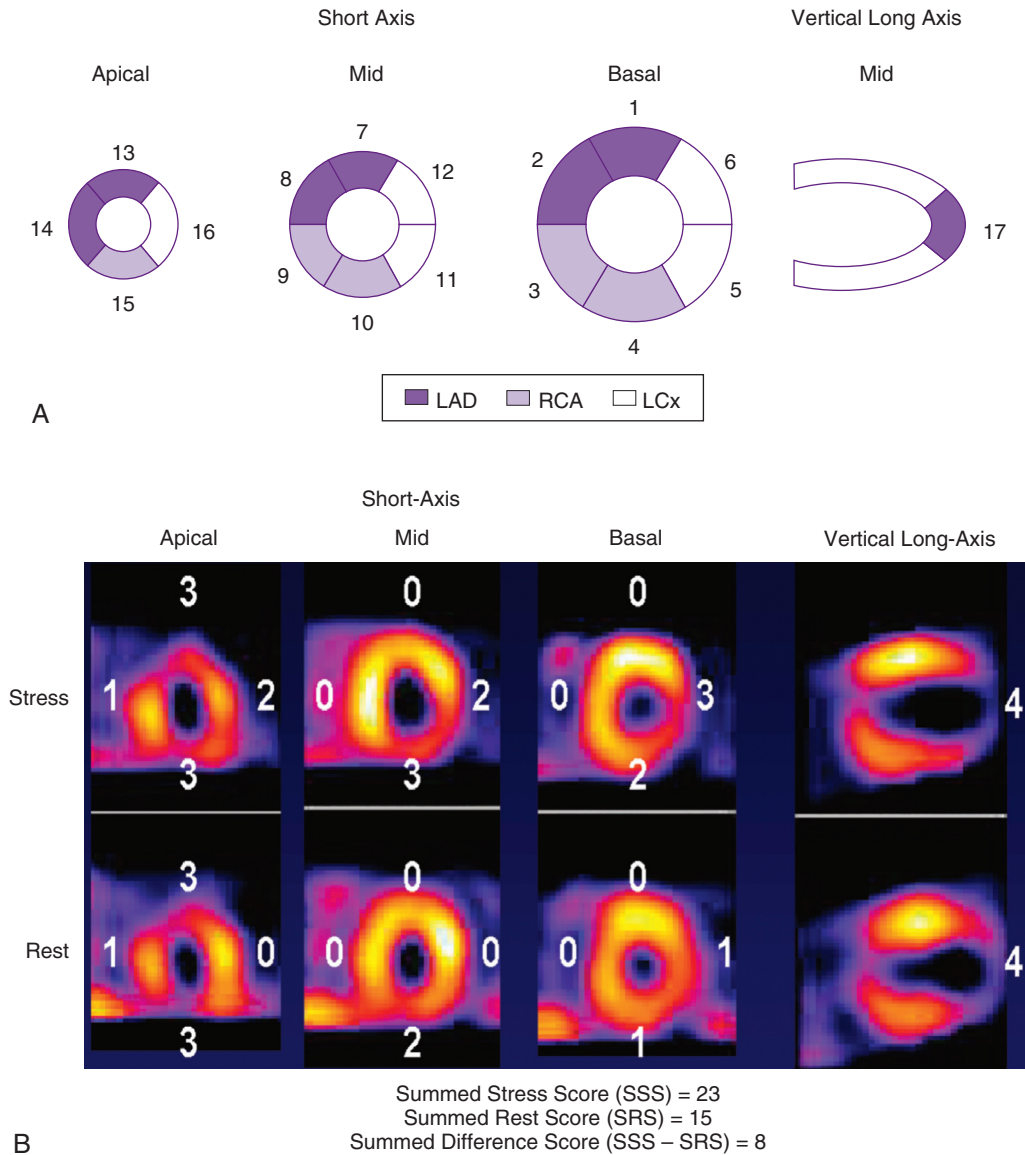

FIGURE 16-7 A, Standard segmental myocardial display for semiquantitative visual analysis in a 16-segment model, with corresponding vascular territory schematic. **B**, Segmental scoring of a patient whose stress and rest SPECT perfusion images show a severe apical fixed defect (in the vertical long axis), extending into the inferoapical and anteroapical walls (in the apical short axis), with evidence of reversible defects in the inferior and lateral walls (in the mid and basal short axis). The summed stress score (SSS = 23) represents extensive perfusion abnormality at stress (reflecting ischemia and infarct); the summed rest score (SRS = 15) represents the extent of infarct; and the summed difference score (SDS = SSS - SRS = 8) represents the extent of ischemia. LAD = left anterior descending (artery); LCX = left circumflex (coronary artery); RCA = right coronary artery.

FIGURE 16-8 Example of a bull's-eye polar plot for a patient with a reversible defect of the inferolateral wall (arrow on the stress bull's-eye plot, upper left). The blackout area (on the extent blackout plot, lower left) represents the myocardium that falls below the lower limits of normal; in the reversibility plot (lower right), the white area represents the extent of that abnormality that is reversible (ischemic) on rest imaging. (Images courtesy Ernest Garcia, PhD.)

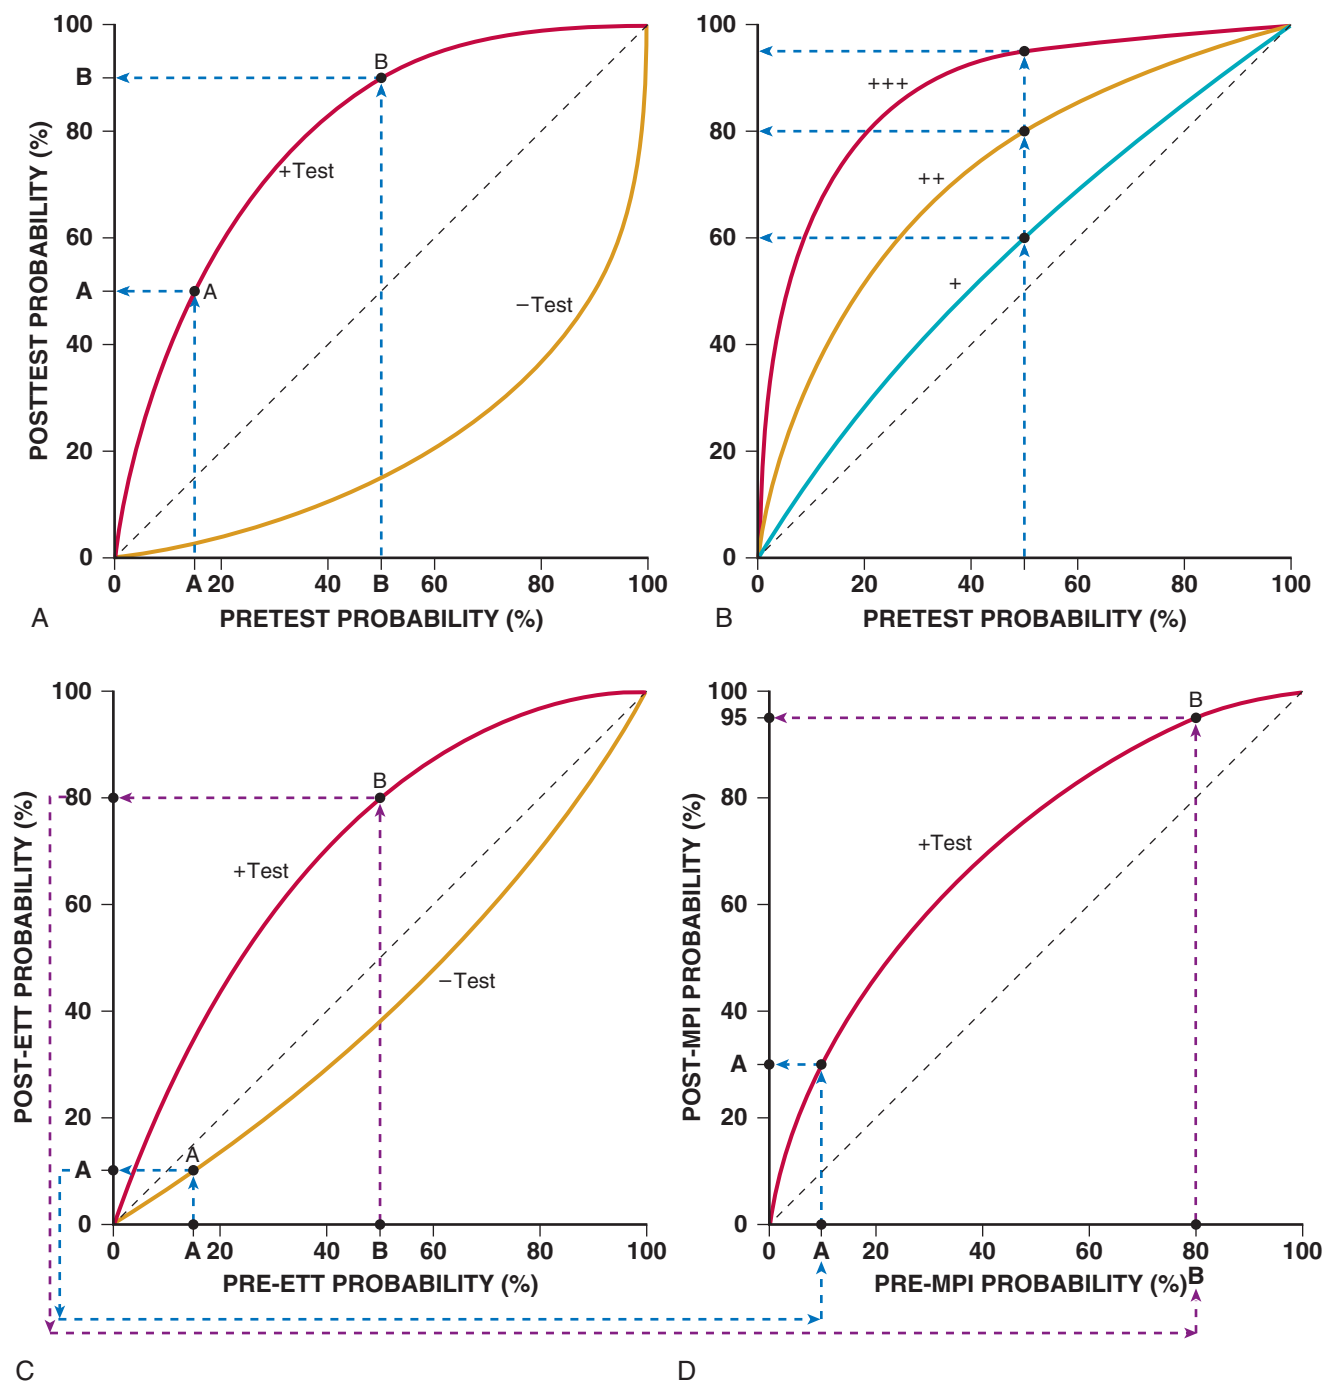

FIGURE 16-9 The influence of the pretest probability on posttest interpretation and application of Bayes' theorem. **A**, For a patient with a low pretest probability of disease (point A at 15% on the x axis) with a positive test result, the posttest probability of disease (point A at 50% on the y axis) is lower than for a different patient with a higher pretest probability with the same positive test result (point B at 50% pretest probability on the x axis, 90% post-test probability on the y axis). In **B**, the "test positive" curve can be thought of as a family of curves influenced by how strongly positive the images can be. For a given pretest probability, the posttest probability becomes progressively higher as the image becomes more strongly abnormal. For a borderline abnormal study (+ curve), the post-test probability may be only slightly higher than the pretest value. For a strongly positive study (+++ curve), the posttest probability is very high no matter what the pretest probability. **C**, **D**, Sequential application of Bayes' theorem. For a young patient with nonanginal chest pain, the pretest probability of CAD is low (approximately 15%, point A on the x axis in **C**). If the patient undergoes an exercise treadmill test (ETT) and exercises to a good workload with no symptoms and no electrocardiographic change, the post-ETT probability is even lower (10% on the y axis in **C**). The post-ETT probability then becomes the pre-MPI probability, as seen in **D** (point A on the x axis). A "positive" MPI test result is still associated with a relative low posttest probability of CAD (point A at 30% probability on the y axis). If reported as positive, there is actually a greater chance that such a result represents a false-positive result (70%) as opposed to a true-positive result (30%). For an older patient with a history of chest pain (higher pretest probability, point B on the x axis in **C**) in whom treadmill exercise reproduces those symptoms, with positive ECG changes, the post-ETT probability rises (point B on the y axis in **C**), and that becomes the high pre-MPI probability (point B on the x axis in **D**). Thus the same MPI results are far more likely to represent a true-positive finding (point B on the y axis in **D**, 95%) and less likely to represent a false-positive study (5%).

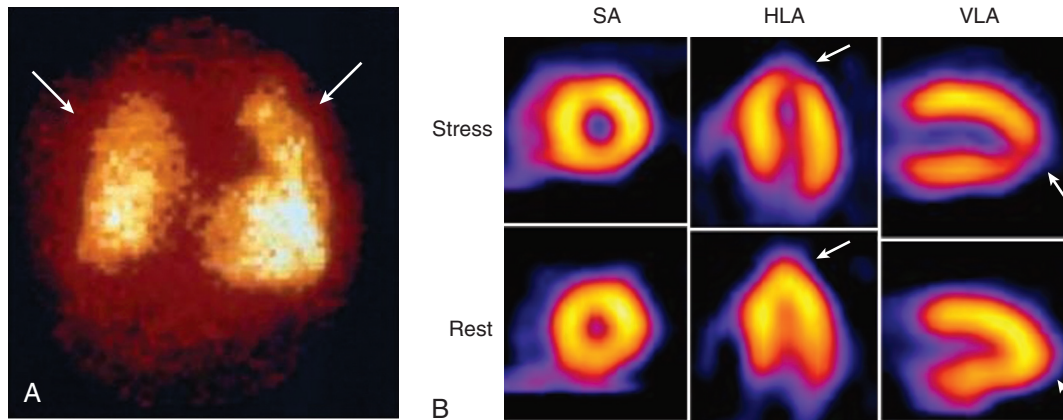

FIGURE 16-10 **A**, Increased lung uptake of ^{201}Tl (arrows) on planar imaging, viewed in the anterior projection. Lung uptake such as this pattern is associated with extensive CAD and an adverse prognosis. **B**, Apical reversible perfusion pattern consistent with ischemia (arrows) in the territory of the LAD artery. There is also transient ischemic dilation (TID), as the left ventricular cavity is larger (appears more dilated) in the stress images than in the rest images in all three tomographic views. The quantitative TID ratio was high at 1.49. Even though the perfusion pattern by itself suggests single-vessel LAD disease, the presence of TID makes the probability of multivessel disease more likely. HLA = horizontal long-axis view; SA = short-axis view; VLA = vertical long-axis view.

Lung Uptake

In some patients, substantial tracer uptake is apparent throughout the lung fields after stress that is not present at rest (**Fig. 16-10A**). Patients with lung uptake often have severe multivessel disease and exhibit elevation of pulmonary capillary wedge pressure and decreases in ejection fraction (EF) during exercise, all implying extensive myocardial ischemia.⁶ It is likely that ischemia-induced elevation in left atrial and pulmonary pressures slows pulmonary transit of the tracer, allowing more time for extraction or transudation into the interstitial spaces of the lung, accounting for this imaging sign.

Lung uptake of ^{201}Tl has been more extensively validated than lung uptake of the $^{99\text{mTc}}$ tracers sestamibi and tetrofosmin. Splanchnic or background activity is minimal after thallium stress injection, allowing image acquisition earlier after stress. In addition, the redistribution properties of thallium mandate that imaging begin relatively early after stress, so lung uptake may be more apparent.

With the $^{99\text{mTc}}$ perfusion tracers, liver uptake is more prominent than that in the heart immediately after injection; accordingly, image acquisition should begin 15 to 30 minutes after exercise stress injection and 30 to 60 minutes after pharmacologic stress.⁶ Thus lung uptake, even if it had been present early after stress, may be missed with $^{99\text{mTc}}$ tracers because of the more delayed onset of imaging than with thallium.

Transient Ischemic Dilation of the Left Ventricle

Transient ischemic dilation refers to an imaging pattern in which the left ventricle or left ventricular (LV) cavity appears larger on the stress images than on those obtained with the subject at rest¹¹ (**Fig. 16-10B**). For patients in whom the entire left ventricle appears larger during stress, the pathophysiology probably is related to extensive ischemia and prolonged postischemic systolic dysfunction, resulting in a dilated, dysfunctional left ventricle during the stress acquisition relative to the rest acquisition. In other patients, the epicardial silhouette appears similar at stress and at rest, but with apparent dilation of the LV cavity. This pattern probably represents diffuse subendocardial ischemia (relatively less tracer uptake in the subendocardium, creating the appearance of an enlarged LV cavity) and also is associated with severe and extensive CAD. Contemporary processing systems can automatically quantify transient ischemic dilation.

Both lung uptake and transient ischemic dilation provide clues to more extensive CAD than may have been suspected from the perfusion

FIGURE 16-11 Normal variations in SPECT perfusion imaging. **A**, Normal “dropout” of the basal septum (arrows), which would be seen in the most basal short-axis tomograms. **B**, Normal apical thinning (arrows). **C**, The lateral wall often is slightly “hotter” than the septum, another normal variation.

pattern alone. Both signs have been associated with angiographically extensive and severe CAD and with unfavorable long-term outcomes; accordingly, such changes are considered high-risk findings.

Common Normal Variations in SPECT Imaging. Normal variations in perfusion images can be falsely interpreted as a defect. These perturbations from a completely homogeneous tracer pattern throughout the myocardium are related to structural variations of the myocardium as well as to technical factors associated with image acquisition.

One example is the “dropout” of the upper septum secondary to merging of the muscular septum with the membranous septum (**Fig. 16-11A**). Apical thinning is another variation of normal that can be mistaken for a perfusion defect (**Fig. 16-11B**). The apex is anatomically thinner than other myocardial regions, creating this appearance. In normal SPECT images, the lateral wall often may appear brighter than the contralateral septum (**Fig. 16-11C**). This difference is not due to a disparity in lateral versus septal wall myocardial blood flow. Rather, during a SPECT acquisition, the camera is physically closer to the lateral myocardial wall (in proximity to the lateral chest wall) than to the septum, so that the image is subject to less soft tissue attenuation and the acquisition is associated with more efficient count capture. A careful review of the data for a series of normal volunteers or subjects with a low probability of CAD with one’s own equipment is an

important step in minimizing the influence of these normal variations on the sensitivity and specificity for detection of CAD.

Technical Artifacts Affecting Image Interpretation. *Photon attenuation* refers to undetected events in the heart due to interaction of photons with the intervening soft tissue, breast, or diaphragm. Attenuation of photons can produce artifactual defects in both positron emission tomography (PET) and SPECT cardiac imaging that mimic true myocardial perfusion defects, thereby reducing specificity (i.e., increasing false-positive findings).

Breast Attenuation. In patients with large or dense breasts, significant attenuation may create artifacts varying considerably in their appearance and location (Fig. 16-12). A review of the cine display of the raw projection images may reveal the presence of potential breast attenuation.⁷ The availability of gender-matched quantitative databases has had a favorable although modest impact on this issue, because such databases generally consist of subjects who are of average body and breast size.

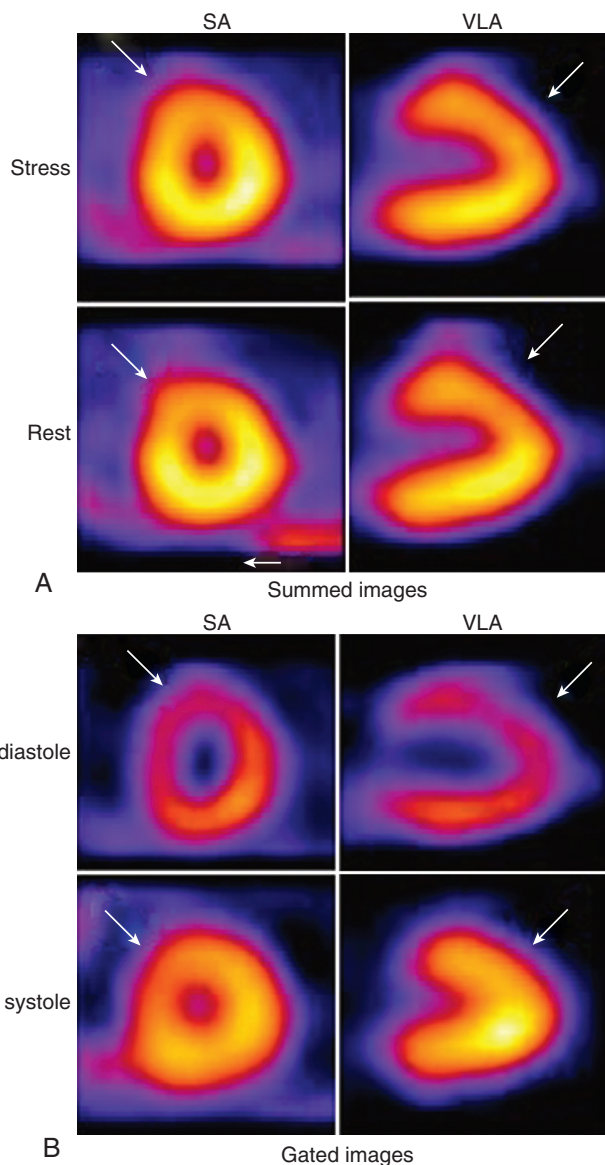

FIGURE 16-12 Differential diagnosis of a mild fixed defect by incorporation of gated functional images. **A**, The summed images demonstrate a mild fixed anterior and anteroseptal defect in the short-axis (SA) and vertical long-axis (VLA) views (arrows). There was a suggestion of breast shadowing on review of the raw cine images (not shown). Thus this defect may represent either a nontransmural anterior infarct or an artifact consistent with breast attenuation. In such cases, the gated SPECT functional images are helpful in making this distinction. **B**, In the gated images, the same SA and VLA views are shown but frozen in end diastole and end systole. In both views, wall thickening from end diastole to end systole (arrows) appears normal. This appearance is most consistent with an attenuation artifact, because an infarct would be expected to result in abnormal wall thickening.

Several approaches to minimizing the impact of breast tissue have been taken to improve specificity (lowering the false-positive rate) in women. Most well validated is ECG-gated SPECT imaging with ^{99m}Tc-based agents (see further on). The presence of preserved wall motion in the setting of a mildly to moderately severe fixed defect of the anterior or anterolateral wall suggests the absence of infarction and supports the interpretation of attenuation artifact (see Fig. 16-12). Specificity for ruling out CAD in women has been improved significantly with this technique,⁶ as discussed subsequently.

Inferior Wall Attenuation. Inferior wall attenuation artifacts are commonly encountered in SPECT imaging. This artifact may be caused by extracardiac structures, such as the diaphragm overlapping the inferior wall (Fig. 16-13). In addition, during a SPECT acquisition, the longer distance from the inferior wall to the camera means that photons must traverse a greater thickness of tissue before reaching the detectors, which may increase the degree of scatter and attenuation.

As with breast attenuation artifact detection, the demonstration of preserved wall thickening by gated SPECT imaging may be helpful in distinguishing attenuation artifact from infarct. The patient's positioning also may minimize the degree of attenuation. By imaging the patient in the prone position,^{2,7} the inferior wall is shifted away from the diaphragm and is therefore less subject to attenuation (see Fig. 16-13).

Artifacts Related to Extracardiac Tracer Uptake. Tracer uptake in extracardiac structures can cause artifacts in SPECT images. When such a structure is near the heart, increased counts may reach the detector, falsely elevating the number of counts the system assigns to the nearby cardiac wall, so that the cardiac region is displayed as falsely "hotter." A second possibility occurs when a nearby hot extracardiac structure causes a "ramp filter" or "negative lobe" artifact.² This artifact is due to a hot extracardiac structure "stealing" counts from the heart during the calculation of the summed SPECT images. The adjacent myocardium appears falsely "cool." If substantial extracardiac uptake is noted, image acquisition can be repeated after waiting a longer time before imaging. Having the patient drink cold water may enhance clearance of tracer from visceral organs, particularly the bowel.

Attenuation Correction Methods

The 511-keV photons emitted by positron-emitting radiotracers in PET imaging are attenuated less per centimeter of soft tissue than are the lower-energy 80- to 140-keV photons typically emitted by SPECT radiotracers. In SPECT imaging, a single photon needs to travel from the heart to the camera; in PET imaging, two coincident photons (i.e., emitted simultaneously) need to travel across the entire body to reach their respective detectors (see later under [Positron Emission](#)

FIGURE 16-13 Left: Attenuation of the inferior basal wall (arrows) possibly related to attenuation by overlying left hemidiaphragm. Most commonly, this appears as a tapering of the inferior wall seen best on the vertical long-axis (VLA) image obtained with the patient supine. Right: One solution to the problem of inferior wall attenuation is reimaging with the patient in the prone position. In this position, the inferior wall is pulled somewhat away from the diaphragm. In this example, the inferior wall appears more normal in the prone acquisition, suggesting that the apparent reduction in counts in the usual supine acquisition represented attenuation artifact.

Tomography). Although the total attenuation may actually be greater for PET than for SPECT, an important distinction in the case of PET is that the attenuation is the same along a projection line (the path the pair of photons traverse) independent of how deep in the body the annihilation took place. Thus, in PET, only the total attenuation through the whole body along a specific direction must be known. On the other hand, in SPECT, it is necessary to know the exact depth along a projection line where the radioactive decay took place in order to correct for attenuation. Therefore attenuation correction for SPECT is theoretically more challenging. In recent years, several approaches to correct for attenuation in both PET and SPECT imaging have emerged, with the goal of “correcting” attenuation artifacts to minimize false-positive defects and to improve specificity.

PET ATTENUATION CORRECTION. To measure the attenuation correction factor, a rod that rotates about the patient is filled with a relatively long-lived positron emitter, germanium-68, or a single photon emitter, cesium-137. The rod is first made to rotate at a fixed speed in the gantry, and total coincident counts are measured without the patient (the blank scan) and repeated with the patient (the transmission scan). The ratio of coincident counts of blank scan and those of transmission scan yields the array of attenuation correction factors needed to correct each projection line. Once each projection line has been corrected for attenuation (and scatter), the emission data may be reconstructed into an attenuation-corrected emission image for clinical interpretation. So long as the patient does not move during the scanning procedure, cardiac PET images will be free from attenuation artifacts.

SPECT ATTENUATION CORRECTION. Approaches similar to PET attenuation correction have been attempted to correct attenuation artifacts in SPECT, but these methods have not been widely adopted because the problem of attenuation correction is fundamentally more challenging in SPECT than in PET. A number of commercially available SPECT gamma cameras have the ability to acquire transmission data and to perform attenuation correction. Several published studies suggest that incorporating attenuation correction into SPECT interpretation may increase the specificity of CAD diagnosis. However, the increased cost of SPECT attenuation correction systems and the additional time required to quality control, acquire, and process studies are factors that have slowed the widespread deployment of this technology.

Accurate attenuation correction with SPECT requires both emission and transmission acquisitions from a single study, and there are a number of potential approaches to accomplish this. The first is a sequential attenuation correction, which can be done with the emission acquisition (the clinical imaging data) after the transmission scan. However, registration between the two acquisitions can be challenging. A second approach is “interleaved” attenuation correction, in which emission and transmission scans are acquired sequentially, at each stop. Although this reduces the emission-transmission misalignment, the acquisition time is significantly longer. The third approach is simultaneous attenuation correction, which reduces the length of the study as well as emission-transmission misalignment. When a two-headed (90-degree) or three-headed gamma camera is used, one of the heads can be dedicated to acquire the transmission data and the other head (or two) to acquire the emission data. However, crosstalk by scattered photons between the emission and transmission photons unavoidably degrades the acquired data. For three-headed SPECT cameras, a line source can be added at one of the gaps between the three camera heads. In this approach, the opposing camera head with a fan beam collimator is then used to detect the transmitted photons. Because the fan beam collimator focuses down to a line in approximately 50 cm, it is possible that a portion of the patient’s body will not intersect the fan beam and thus be out of the camera’s field of view. This limitation can lead to loss of data, termed truncation artifact, in reconstruction of the attenuation image. Although a number of schemes have been proposed to account for the truncation artifact, none has proved to be clinically robust. Clinical validation has been performed for several but not all of the commercially available systems described. Despite these technical challenges, the application of attenuation correction in

FIGURE 16-14 Impact of attenuation correction (AC). The non-AC images (top row) include examples of an inferior defect (left column) and an anterior defect (right column), which may represent a true perfusion abnormality, respectively, or may represent a true perfusion abnormality. With the application of AC (bottom row), both images become normal in appearance, suggesting that the abnormalities in the non-AC images were highly likely to represent artifact. (Courtesy Ernest Garcia, PhD.)

multicenter clinical trials, with different hardware and software approaches, has been shown to add to the diagnostic accuracy of stress myocardial perfusion SPECT, predominantly by improving specificity (Fig. 16-14). Consequently, the ASNC and the Society of Nuclear Medicine published a joint statement with the recommendation that the weight of current evidence is in favor of applying attenuation correction in addition to ECG gating with SPECT MPI to optimize diagnostic accuracy.¹² This recommendation, however, presumes that the attenuation correction methodology is applied by personnel highly knowledgeable about the technique and its stringent quality control.

Gated SPECT Imaging

An important advance in the use and application of SPECT MPI has been the incorporation of ECG-gated SPECT perfusion imaging for simultaneous assessment of LV function and perfusion. Before the use of gated SPECT, comprehensive information on both perfusion and function required separate testing modalities, such as SPECT MPI and separate radionuclide ventriculography (RVG) or echocardiography.

To assess parameters of cardiac function with echocardiography (see Chapter 14), LV endocardial borders are drawn over several beats to derive parameters such as EF. With contrast left ventriculography, endocardial borders are drawn for either one beat or an average of several beats to calculate EF. In contrast, with MPI the number of counts recorded during any individual cardiac cycle is insufficient to create an interpretable image for assessment of ventricular function. This limitation is overcome with the use of a technique known as ECG gating (Fig. 16-15), in which an average cardiac cycle is created representing the average of several hundred beats acquired during a period of 8 to 15 minutes.

During an ECG-gated image acquisition, the patient’s ECG is monitored simultaneously. As the peak of an R wave is detected, the “gate” opens and a set number of milliseconds of imaging information is stored in a “frame.” For a typical gated SPECT acquisition, each R-R interval is divided into eight frames. For example, if the patient’s heart rate at rest is 60 beats/min (1000 milliseconds per beat), an eight-frame acquisition across the cardiac cycle comprises 125 milliseconds per frame. After the first 125 milliseconds of imaging data have been recorded in frame 1, the gate closes and then instantly reopens, allowing the second 125 milliseconds of information to be recorded in frame 2 (Fig. 16-15A). This sequence continues through the

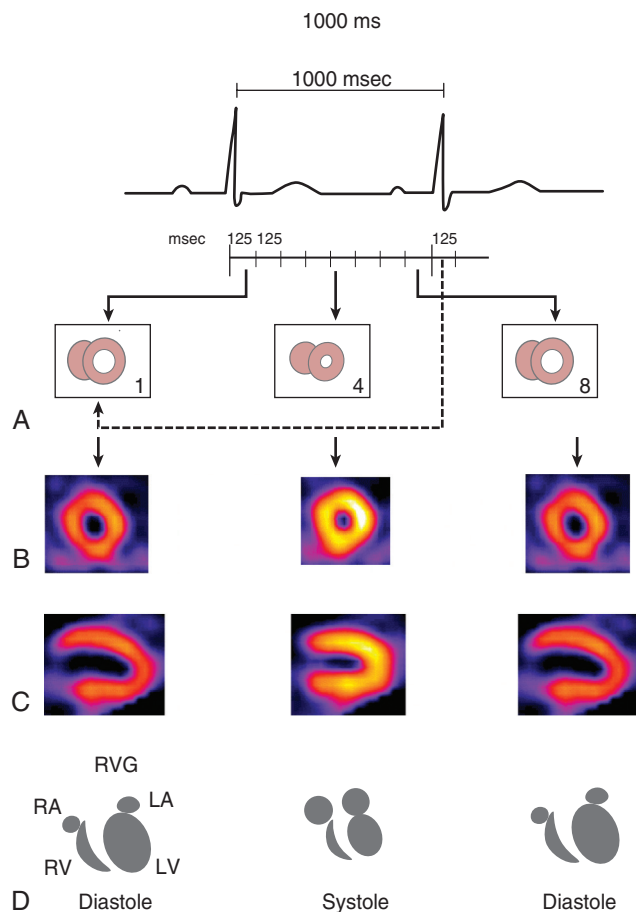

FIGURE 16-15 Basis for the technique of ECG gating. **A**, The scintigraphic acquisition data are collected in conjunction with the electrocardiogram. The R-R interval is divided into a prespecified number of "frames" (in this example, eight frames). At a heart rate of 60 beats/min (1000 msec/beat), each of the eight frames would comprise 125 milliseconds. For the first 125 milliseconds after the peak of the initial R wave, all imaging data are recorded in frame 1; the second 125 milliseconds are recorded in frame 2, and so on, until the peak of the next R wave is detected, and this is repeated for each beat in the acquisition. Frame 1 thus represents the end-diastolic events, and one of the frames in the middle of the acquisition (frame 4 in this example) represents end-systolic events. **B**, Examples of gated SPECT perfusion imaging. Short-axis images are seen at end diastole and at end systole. **C**, Similar timing with images displayed in the vertical long-axis orientation. Visually, wall thickening and brightening are seen across the course of systole. These events represent changes in regional and global function across the cardiac cycle. **D**, ECG-gated equilibrium radionuclide ventriculographic schematic images are shown at diastole and at end systole. LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle. (Modified from Germano G, Berman DS: Acquisition and processing for gated SPECT: Technical aspects. In Germano G, Berman DS [eds]: *Clinical Gated Cardiac SPECT*. Armonk, NY, Futura, 1999, pp 93-114.)

prespecified number of frames throughout the cardiac cycle. When the R wave of the next beat is detected by the ECG-gated system, the sequence is repeated, and so on for each of the many beats that occurs throughout the image acquisition.

When several hundred beats have been recorded, an average cardiac cycle representing all the recorded beats can be reconstructed by redisplaying the frames sequentially in a cine or movie format.¹³ The first few frames represent systolic events, and the latter frames represent diastolic events (see Fig. 16-15A).

High-quality ECG-gated images require that the cardiac cycles that are included have reasonably homogeneous beat lengths. This usually is accomplished by beat-length windowing, whereby the computer acquisition system is programmed to accept beats of only certain cycle lengths into the acquisition. Typically, cycles with the beat length represented by the average heart rate of the patient (1000 milliseconds in the preceding example), along with cycles fluctuating up to 10% to 15% around the average beat length, are allowed into

FIGURE 16-16 Examples of regional dysfunction detected by ECG-gated SPECT perfusion imaging. **A**, The severely hypokinetic inferior region appears to brighten less (arrows) than the other regions from diastole to systole. The lateral wall also brightens less than the normal septum and would therefore be interpreted as hypokinetic. **B**, The akinetic apex in the horizontal long axis (arrows) shows no apparent change from diastole to systole, in contrast with the normally thickening (brightening) lateral wall. SA = short axis; HLA = horizontal long axis.

the acquisition. Cardiac cycles with cycle lengths above or below that limit are rejected. For example, the short cardiac cycle from the R wave of a normal beat to the R wave of a premature ventricular contraction (PVC) would not be allowed into the acquisition, nor would the long cycle representing the post-PVC pause. This makes physiologic sense; the short pre-PVC beat and the more prolonged post-PVC beat have distinctly different systolic and diastolic characteristics from those of the beats occurring during normal sinus rhythm.

Gated SPECT Interpretation of Regional Wall Motion

Normal regional systolic function is depicted as brightening of the wall during systole^{2,13} (Fig. 16-15B). The wall appears to thicken, with apparent endocardial excursion. Assessment of regional LV function by gated SPECT imaging is based on an effect known in imaging physics as the partial volume effect, sometimes referred to as the recovery coefficient effect. When objects being imaged fall below a certain thickness threshold, count (or photon) recovery from the object is related not only to the tracer concentration within that object but also to the thickness of the object.¹³ For SPECT imaging, usually all myocardial wall thicknesses fall below that threshold. Although tracer concentration within the myocardium is constant during a gated SPECT image acquisition, the recovery of counts (and thus the brightness of the object being imaged) is related to wall thickness. Hence, during systolic wall thickening, it appears that the LV wall becomes brighter and thicker, even though the isotope concentration per gram of myocardial tissue is actually unchanged. This principle forms the basis for gated SPECT imaging.

Regional myocardial function usually is assessed visually, in a manner similar to the analysis performed in echocardiography. Regions that brighten normally have normal regional systolic performance, and those with diminished but apparent brightening are labeled hypokinetic. Regions with slight brightening are interpreted as severely hypokinetic, and regions with no apparent brightening as akinetic (Fig. 16-16). Regional function also can be analyzed by quantitative techniques and displayed in a polar map format.

Gated SPECT Assessment of Global Left Ventricular Function

All contemporary camera-computer systems have software capable of quantifying global LV function and computing the EF. These computer-based methodologies are fully automated and thus highly reproducible. The most common method involves automated interrogation of the apparent epicardial and endocardial borders of all of

defects, ECG-gated SPECT imaging provides robust, reproducible estimates of LVEF.

The incorporation of ECG-gated SPECT imaging into a SPECT acquisition is now routine in MPI and is recommended as standard by contemporary guidelines.^{2,7} As discussed subsequently, the addition of LV function data to the perfusion information provides incremental and independent prognostic information, in addition to its practical importance in management decisions. Gated SPECT imaging also has been an important advance in helping to differentiate attenuation artifacts from infarct, because regions with persistent low counts that show normal motion and thickening represent soft tissue artifacts rather than scar (see Fig. 16-12). Thus gated SPECT has improved the specificity of perfusion imaging for ruling out CAD, particularly in women.⁷

Planar Myocardial Perfusion Imaging

Before the widespread application of tomographic (SPECT) perfusion imaging techniques, planar imaging was the standard acquisition and display methodology. In planar imaging, three separate two-dimensional images are obtained with the gamma camera after radiotracer injection and uptake into the myocardium.² The three standard views are an anterior, a left anterior oblique, and a more lateral view (Fig. e16-2).

With planar imaging, the imaging views are standard and prespecified, and the reader must account for the different orientations of the heart in assigning regional abnormalities. By contrast, because the tomographic SPECT slices are constructed along orthogonal planes that are perpendicular and parallel to an assigned long axis, SPECT images are oriented in a uniform manner for display and interpretation without influence by the individual patient's cardiac orientation.

An advantage of planar imaging over SPECT imaging is its simplicity. Each of the three views can be acquired during 5 to 8 minutes with patients lying on a table with their

arms by their sides. Planar imaging is less affected by patient motion than is SPECT imaging. With planar imaging, extensive image processing is not required as with SPECT, so there are fewer sources of potential error and artifact. Owing to its two-dimensional nature, however, planar imaging, in each of the standard views, generates substantial overlap of myocardial regions, with less differentiation of smaller and particularly milder perfusion abnormalities. The more standard orientation of SPECT imaging lends itself to easier understanding of the localization of perfusion abnormalities.

The original data on the sensitivity and specificity of perfusion imaging for CAD, as well as the prognostic value of perfusion imaging, were developed with planar imaging and later revalidated with SPECT imaging. In contemporary practice, planar imaging may be used for patients who do not tolerate the position that must be maintained during a SPECT acquisition, those who have difficulty coping with

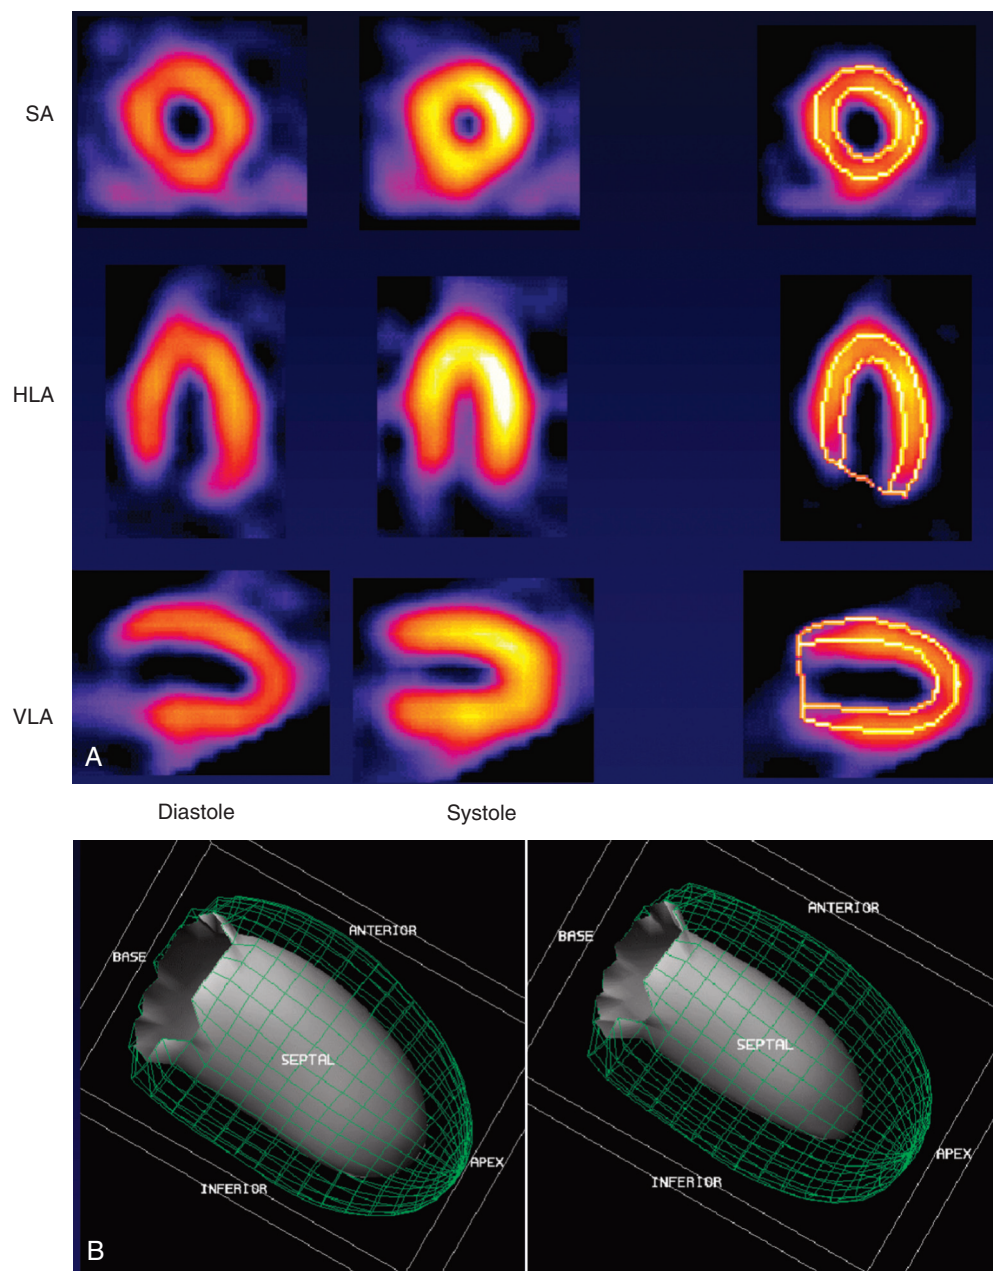

FIGURE 16-17 A, ECG-gated SPECT perfusion images in short axis (SA), vertical long-axis (VLA), and horizontal long-axis (HLA) views, shown frozen at end diastole (left column) and end systole (middle column). Endocardial and epicardial borders are shown on the diastolic frames as automatically assigned by the software analysis program (right column). **B**, From the contours that are created from all of the two-dimensional tomograms, a three-dimensionally surface-rendered image of the left ventricle can be created and displayed in multiple orientations, here frozen at end diastole (left) and end systole (right). The green “mesh” represents the epicardium, and the gray surface represents the endocardium. EF is quantified from the volume change. During image interpretation, gated SPECT images are displayed in the cine format as an endless loop movie, rather than as the still frames depicted here.

the tomograms in all three orthogonal planes (Fig. 16-17A). These multiple two-dimensional contours are then reconstructed to create a surface-rendered three-dimensional display representing global LV function across the average cardiac cycle (Fig. 16-17B) that can be viewed from any direction by simple maneuvering of the computer display screen or cursor.¹³ The three-dimensional display is accompanied by automated calculation of EF and LV volumes.

EF measurements from automated analysis of ECG-gated SPECT MPI have been extensively validated against those obtained using other quantitative techniques for assessing LV function, such as equilibrium RVG, angiographic contrast left ventriculography, and cardiac magnetic resonance (CMR) (see Chapters 17 and 19).¹³ Across a wide range of LV function, and even in the setting of severe perfusion

FIGURE e16-2 Examples of planar myocardial perfusion imaging. *Top row:* A normal stress planar perfusion study in the anterior, shallow left anterior oblique (LAO), and more lateral views. Tracer uptake is uniform throughout the myocardial walls. *Middle row:* The same normal planar stress perfusion images are shown, with the myocardial walls that are seen in each labeled view. The anterior wall (Ant), apex, and inferior (Inf) walls are seen in the anterior view, as well as RV. The septum (Sept), apex, and lateral walls (Lat) and the RV are seen in the shallow LAO view, and the anterior wall, apex, and inferior walls are seen in the lateral view. *Bottom row:* An abnormal planar study showing a lateral wall stress perfusion defect in the shallow LAO view (arrow), extending into the inferior wall in the lateral view (arrow). Rest images are not shown. (Courtesy Dr. Kim A. Williams.)

presence of the larger SPECT camera so close to the body, or those with large body habitus that surpasses the weight and size limits of SPECT systems.⁷

Quantitative analytical techniques such as the circumferential profile technique were originally developed by use of planar perfusion imaging. As documented in a substantial literature, quantitative analysis applied to planar perfusion imaging yields an improved sensitivity for detection of multivessel CAD.

Radionuclide Ventriculography or Angiography

RVG, also known as radionuclide angiography or blood pool imaging, may be performed using first-pass or by equilibrium-gated techniques.¹⁴ The equilibrium technique often is referred to as *multiple gated acquisition* (MUGA) scanning. Although the two techniques each use specific tracers and data recording methods, they provide similar results for global EF and chamber volumes. Both techniques provide a highly reproducible means to quantify global LV and right ventricular (RV) EF.

Equilibrium Radionuclide Angiography or Ventriculography (Gated Blood Pool Imaging). In equilibrium RVG studies, data are recorded in a computer system synchronized with the R wave of the patient's electrocardiogram, similar to ECG-gated SPECT (see Fig. 16-15). For labeling of the blood pool, ^{99m}Tc is bound to red blood cells or albumin. Image contrast usually is better with ^{99m}Tc-labeled red blood cells, but ^{99m}Tc-labeled albumin is preferable in patients in whom red blood cell labeling may be difficult. Labeling of red blood cells with ^{99m}Tc-pertechnetate requires a reducing agent, stannous pyrophosphate, which is administered 15 to 30 minutes before pertechnetate injection.

Image Acquisition. Although relatively few counts are recorded during a single ECG-gated cardiac cycle, the summation of counts from 800 to 1000 cardiac cycles produces an average cardiac cycle with high resolution. Images of the heart are usually acquired in three standard projections: anterior, "best septal" left anterior oblique (best separation of the left and right ventricles), and left lateral (or left posterior oblique). The minimum framing rate for a rest RVG study is 16 frames/cycle (approximately 50 msec/frame).¹⁴ For quantitative assessment of diastolic indices and regional EF, the framing rate should be increased to 32 frames/cycle (approximately 25 msec/frame). For adequate counting statistics, images are acquired for a preset count of at least 250,000 per frame or count density of 300 counts per pixel, which corresponds to an acquisition time of 5 to 10 minutes per projection. For exercise studies, adequate counts can be obtained in the best septal view with a 2-minute acquisition using a high-sensitivity collimator. Arrhythmias such as multiple PVCs can adversely affect the study if these beats account for more than 10% of the total. In patients with atrial fibrillation, there may be considerable beat-to-beat variability, and the mean EF obtained during the period of acquisition may underestimate the actual LVEF.¹⁴

Image Display and Analysis. Qualitative inspection of equilibrium studies as an endless cinematic loop of the cardiac cycle (see Fig. 16-15D) allows assessment of (1) size of heart chambers and great vessels; (2) regional wall motion; (3) global function (qualitative assessment) (Fig. e16-3); (4) ventricular wall thickness, pericardial effusion, pericardial fat pad, or paracardiac mass; and (5) extracardiac uptake (such as splenomegaly). Quantification of systolic and diastolic indices and volumes is derived from the ventricular time-activity curve,¹⁴ which is analogous to the angiographic time-volume curve (Fig. e16-4). In addition to the time-activity curve, functional images, such as amplitude and phase images, can be produced that have been useful in characterizing regional asynergy and asynchrony.

First-Pass Radionuclide Angiography or Ventriculography. In first-pass RVG studies, the bolus of radioactivity passes initially through the right chambers of the heart, then through the lungs, and finally through the left-sided chambers of the heart. Radiopharmaceuticals used for this purpose must produce adequate counts in a short time at an acceptably low radiation dose to the patient.¹⁴ Although both ^{99m}Tc-diethylenetriaminepentaacetic acid (DTPA) and ^{99m}Tc-pertechnetate have short intravascular residence time, ^{99m}Tc-DTPA is the recommended radionuclide of choice because the DTPA salt enhances renal excretion.

Image Acquisition. Images are acquired very rapidly as the tracer passes through the heart chambers. Separation of the right and left ventricles is achieved because of the temporal separation of the bolus. Image quality is related to the injection technique, which should be rapid (during 2 to 3 seconds) to achieve an uninterrupted bolus (Fig. e16-5). Images are acquired in the supine position after the rapid injection of 10 to 25 mCi of tracer (depending on type of camera/

crystal) through an 18-gauge or larger intravenous catheter placed in the medial antecubital or external jugular vein. The shallow (20- to 30-degree) right anterior oblique projection is used, to optimize separation of the atria and great vessels from the ventricles and to view the ventricles parallel to their long axes. Although the right anterior oblique view maximizes overlap of the right and left ventricles, this is not a problem in most patients because the timing of tracer appearance reliably identifies each chamber sequentially. A 1-mCi tracer dose may be used to ensure proper positioning so that the right and left ventricles are in the field of view.

Image Analysis. To identify the RV and LV phases, regions of interest are drawn around the right and left ventricles at end diastole.¹⁴ Time-activity curves are generated, and cycles around and including the peak time-activity curve are used to calculate EFs. In general, two to five cardiac cycles are summed for the RV phase, and five to seven cycles are summed for the LV phase. From these data, quantitative analysis of LVEF and right ventricular ejection fraction (RVEF) is performed.

Comparison of Equilibrium and First-Pass Techniques. Advantages of the first-pass technique are the high target-to-background ratio, more distinct temporal separation of the cardiac chambers, and rapidity of imaging. RVEF may be more readily assessed by the first-pass technique because of the more distinct separation of this structure from the other chambers with that technique. Advantages of equilibrium technique are the potential for repeated assessment of cardiac function during rapidly varying physiologic conditions, high count density, and acquisition of images in multiple projections. In contemporary practice, the equilibrium technique is performed far more commonly.^{2,7}

Positron Emission Tomography

Because of the quantitative capabilities of PET, measurement of myocardial perfusion and metabolism can be obtained with PET in absolute quantitative terms, a potential advantage compared with SPECT imaging. The radiotracers used in PET are labeled with positron-emitting isotopes that have chemical and physical properties identical to those of naturally occurring elements, such as carbon, oxygen, nitrogen, and fluorine. Incorporation of such elements allows interrogation of physiologically relevant processes in normal and diseased states.⁶ Although most positron-emitting radiotracers are cyclotron produced with short half-lives, the development of generator-produced positron-emitting isotopes, such as rubidium-82 (⁸²Rb), makes it feasible for laboratories to perform cardiac PET studies without an on-site cyclotron.

Clinically available cardiac PET radiotracers fall within two broad categories: those that evaluate myocardial perfusion and those that evaluate myocardial metabolism (Table 16-2).⁶ The perfusion tracers ⁸²Rb and ¹³N-ammonia and the myocardial metabolic tracer 2-¹⁸F-fluoro-2-deoxyglucose (FDG) have received FDA approval.

Image Acquisition

PET employs camera systems designed to optimize the detection of positron-emitting radioisotopes. The process by which a positron-emitting radionuclide attempts to stabilize over time is termed *beta decay*, which occurs when the nucleus of an atom emits a positron, a positively charged beta particle (Fig. 16-18). After a high-energy

TABLE 16-2 Properties of Selected Positron Emission Tomography Tracers

TRACER	PRODUCED	HALF-LIFE	COMPOUND
Perfusion			
¹⁵ O	Cyclotron	2.1 minutes	H ₂ O
¹³ N	Cyclotron	10 minutes	NH ₃
⁸² Rb	Generator	76 seconds	RbCl
Metabolism

FIGURE e16-3 Equilibrium radionuclide ventriculography. The isotope (^{99m}Tc) is labeled to red blood cells, so the images represent the blood “pools” in the left ventricle (LV), the right ventricle (RV), the other cardiac chambers, and the great vessels as well as the spleen. Typically, three views are obtained, as shown. **A**, Normal LV function, with end-diastolic images in the *top row* and end-systolic images in the *bottom row*. LV and RV volumes diminish from diastole to systole. **B**, Images obtained in a patient with LV dysfunction. Significant LV and RV dilation is evident at both end diastole (*top*) and end systole (*bottom*), with severely diminished LV systolic function (i.e., much less volume change from end diastole to end systole compared with the study in **A**). LAO = left anterior oblique.

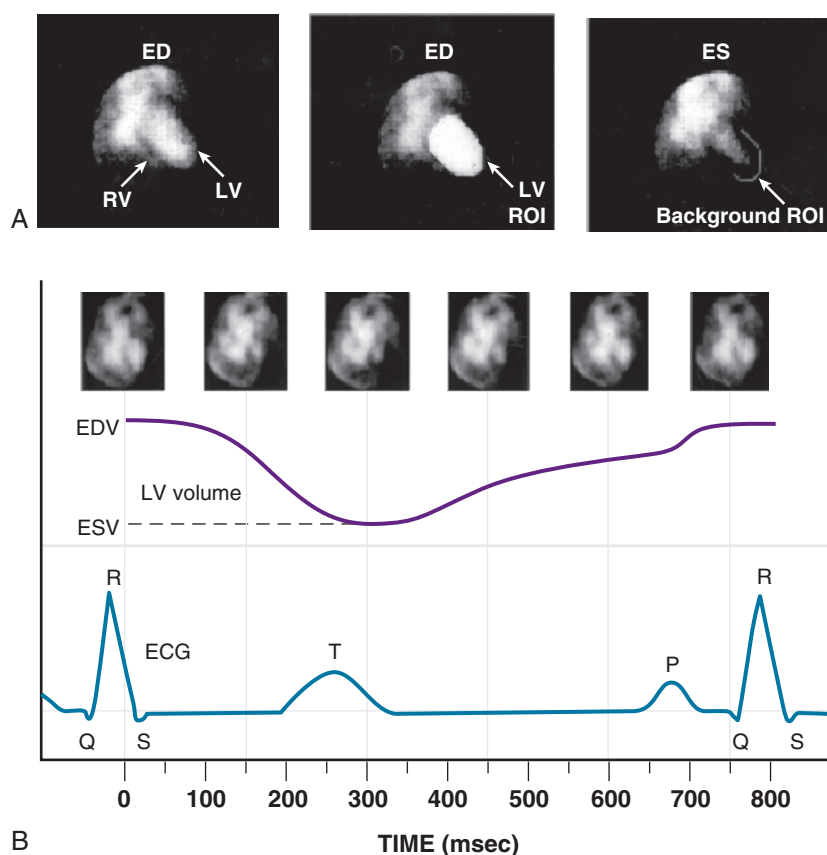

FIGURE e16-4 Quantitative analysis of equilibrium electrocardiogram (ECG)-gated radionuclide ventriculography. **A**, Left anterior oblique view of the left ventricle (LV) and right ventricle (RV) is shown at end diastole (ED) (*left*), with a region of interest (ROI) identifying the LV contour at end diastole (*middle*) and a “background” ROI drawn at end systole (ES) (*right*), used to correct for count activity in front of and behind the LV. **B**, A time-activity curve illustrates the change in counts within the ROIs shown in **A** across a cardiac cycle. Because count activity is related to LV chamber volume, the time-activity curve represents the relative volume change of the LV chamber across a cardiac cycle, from end diastole to end systole and back to end diastole. EDV = end-diastolic volume; ESV = end-systolic volume. (From Green MV, Bacharach SL, Douglas MA, et al: The measurement of left ventricular function and the detection of wall motion abnormalities with high temporal resolution ECG-gated scintigraphic angiocardiology. *IEEE Trans Nucl Sci* 23:1257, 1976.)

FIGURE e16-5 First-pass radionuclide ventriculography. Individual frames from a first-pass acquisition, illustrating the path of the bolus isotope through the superior vena cava (SVC), the right atrium (RA), the right ventricle (RV), the pulmonary outflow tract and lungs (pulmonary artery [PA]), the left atrium (LA), and the LV phase, from which the isotope bolus is then distributed systemically.

FIGURE 16-18 Schematic of positron and electron beta particle emission, with detection by a coincidence camera, as the basis of PET imaging.

positron is emitted from a nucleus, it travels a few millimeters in tissue and ultimately collides with an electron (a negatively charged beta particle). This collision results in complete annihilation of both the positron and the electron, with conversion to energy in the form of electromagnetic radiation composed of two high-energy gamma rays, each with 511-keV energy. The discharged gamma rays travel in perfectly opposite directions (180 degrees from each other). PET detectors can be programmed to register only events with temporal coincidence of photons that strike at directly opposing detectors. The outcome of such selective coincidence detection is an improvement in spatial and temporal resolution for PET over that achieved with SPECT imaging.¹⁵ Unlike the procedure in SPECT, in which an extrinsic collimator is used to limit the direction at which photons enter the detector, the coincidence detection with PET provides "intrinsic" collimation and improves the sensitivity of the camera.

In addition, an important distinction between PET and SPECT is in the ease of labeling primary substrates for energy metabolism and membrane receptor subtypes in the heart, allowing the interrogation of such physiologic pathways *in vivo* with PET. Moreover, dynamic mode PET scanning permits potential analysis of the change in tracer content in a specific region of interest in the heart with time, allowing potential interrogation of the rate of change of a physiologic process.

Image Analysis

Emission data are displayed as tomograms in the horizontal and vertical long-axis and short-axis views, as in SPECT display.¹⁵ If the data are acquired in dynamic mode, with appropriate mathematical modeling, myocardial perfusion and metabolic data can be displayed in absolute terms: in milliliters per gram per minute for blood flow and moles per gram per minute for metabolism.

PET Perfusion Tracers

PET perfusion tracers can be divided into two types: (1) freely diffusible tracers, which accumulate and wash out from myocardial tissue as a function of blood flow, and (2) nondiffusible tracers, characterized by retention in myocardial tissue as a function of blood flow.⁶

The rapid physiologic washout of the freely diffusible tracers, such as ^{15}O -water, makes it possible to repeat studies in rapid sequence. The images of the distribution of such tracers are usually not visually meaningful; mathematical modeling is done to arrive at flow values at each pixel. An advantage of freely diffusible tracers is that they do not depend on a metabolic trapping mechanism, which might change as a function of a changing metabolic environment.

The nondiffusible flow tracers are easier to image, because the tracer is retained in myocardium for a reasonable length of time. ^{82}Rb and ^{13}N -ammonia fall into this second category of flow tracers, the more microsphere-like flow tracers. ^{82}Rb is a cation, with biologic properties similar to those of potassium and thallium, and uptake across the sarcolemmal membrane reflects active transport by the $\text{Na}^+\text{K}^+\text{ATPase}$ pump. In experimental studies, its extraction fraction does not change significantly over a wide range of metabolic conditions. However, the very short half-life of 75 seconds for ^{82}Rb means that any trapped ^{82}Rb quickly disappears from the myocardium by physical decay. Despite its short half-life, ^{82}Rb is easily obtained, because it is generator-produced, and it can be used clinically without the need for an on-site cyclotron.

^{13}N -ammonia is an extractable perfusion tracer, with a physical half-life of 10 minutes. Its transport across cell membranes may occur by passive diffusion or by the active Na^+K^+ transport mechanism. Retention of ^{13}N -ammonia in the myocyte involves metabolic trapping. As with ^{82}Rb , myocardial uptake of ammonia reflects absolute blood flows up to 2 to 3 mL/g/min and plateaus at more hyperemic flows. The use of this tracer to assess myocardial blood flow has been extensively validated in both experimental and clinical studies.¹⁵

PET Perfusion Tracers: Research Directions

^{18}F -labeled fluorobenzyl triphenyl phosphonium, originally developed for measurement of the mitochondrial membrane potential, has been introduced for MPI with PET.¹⁶ The currently available PET myocardial perfusion tracers, ^{82}Rb chloride and ^{13}N -ammonia, have short physical half-lives, so their use requires either an on-site cyclotron or generator, thereby limiting their widespread clinical application. The

longer half-life of ^{18}F (110 minutes) allows the possibility of distribution as a single-dose unit on a daily basis, which may facilitate the clinical application of myocardial perfusion PET imaging. Moreover, the longer half-life of ^{18}F would allow assessment of perfusion during treadmill exercise, rather than with vasodilator stress alone, as is currently the case with ^{82}Rb PET.

One such agent, flurpiridaz F-18, has been studied in a phase II trial in 143 patients who underwent rest-stress PET perfusion imaging with this agent as well as $^{99\text{mTc}}$ SPECT rest-stress perfusion imaging. In blinded reading, image quality and diagnostic certainty were higher with the PET agent, and sensitivity to detect CAD among those undergoing angiography was higher, at similar specificity. Among patients with CAD on angiography, the extent of perfusion abnormality was larger with the PET agent. Larger trials are under way.¹⁷

Clinical Application of PET Perfusion Imaging

^{82}Rb and ^{13}N -ammonia are the two PET tracers that have received FDA approval for clinical application to assess myocardial perfusion. Advantages of PET perfusion imaging over SPECT include higher spatial resolution, improved attenuation and scatter correction, and potential for quantifying regional blood flow. As a result, a number of clinical studies with either ^{82}Rb or ^{13}N -ammonia PET have shown an improvement in either the sensitivity or specificity (as high as 95%) for detection of CAD compared with SPECT (Fig. 16-19). However, the widespread use of PET myocardial perfusion studies in the clinical setting has been hampered by the requirement of an on-site cyclotron for ^{13}N -ammonia and the high cost of monthly generator replacement for ^{82}Rb . Moreover, the relatively short half-lives of both ^{82}Rb and ^{13}N -ammonia limit the utility of PET perfusion studies to patients undergoing pharmacologic stress only. Because the exercise component of MPI studies has independent prognostic and diagnostic value, this represents an important limitation. On the other hand, the potential for quantifying myocardial blood flow and blood flow reserve in absolute terms is highly desirable, with potential clinical applications. For example, patients with multivessel CAD may have uniform decrease in flow reserve, and the relative perfusion data from SPECT may fail to detect this “balanced” ischemia. At the other extreme, detection of mild abnormalities in myocardial blood flow reserve with PET provides the potential for early identification of CAD characterized by endothelial dysfunction in asymptomatic patients with elevated cholesterol, smoking, hypertension, and insulin resistance. Studies also have shown that abnormal blood flow reserve by PET may be predictive of future cardiovascular outcome among patients with cardiomyopathies in the absence of CAD, such as patients with idiopathic dilated cardiomyopathy¹⁸ and hypertrophic cardiomyopathy¹⁹ (see Chapters 65 and 66).

PET Tracers of Myocardial Metabolism

PET is uniquely positioned to investigate alterations in myocardial metabolism and cellular physiology. Tracers for these applications

are discussed in detail further on (see under Assessment of Myocardial Cellular Metabolism and Physiology).

Combined PET-CT and SPECT-CT Scanners

Scanners that combine PET or SPECT technology with radiographic computed tomography (CT) provide a tool for obtaining complementary anatomic and functional information in a single imaging session. CT angiography provides information on the presence and extent of luminal narrowing of epicardial coronary arteries with high sensitivity and specificity (see Chapter 18), whereas PET and SPECT provide information on the downstream functional consequences of anatomic lesions. Cardiac CT angiography is suited to determine whether an “obstructive” coronary artery stenosis is present, although the ability to accurately determine stenosis severity is limited with current-generation CT angiography systems. PET and SPECT, on the other hand, are more suited to determine if such a stenosis is physiologically significant regarding limitation of flow reserve. With the advent of hybrid PET-CT and SPECT-CT systems, such complementary information of anatomy and physiology can be realized immediately, at the same imaging session. The combination of these anatomic and functional modalities is particularly relevant in patients who have an intermediate finding on either SPECT-PET or CT angiography. The advantage afforded by the combined scanner is that the corresponding images are spatially aligned and can be acquired during a single imaging session (Fig. 16-20).

CT Attenuation Correction for PET. A subsidiary benefit of hybrid PET-CT and SPECT-CT imaging systems is in the potential to use the CT image to create the attenuation map for the MPI data. This approach has allowed the replacement of germanium-68 or cesium-137 transmission scans with faster CT scans, reducing the overall duration of the PET procedure. One potential problem of using fast CT scans for attenuation correction, however, is the motion of the organs during respiration. The CT scanner “freezes” the heart, lungs, and liver at one point in the respiratory cycle, whereas the PET emission data are averaged over many respiratory cycles. Methods using respiratory gating to correct this problem are currently under investigation.

At present, the decision of whether a particular patient is a candidate for PET alone, CT angiography alone, or hybrid PET-CT depends on multiple factors. The age of the patient, underlying irregular heart rhythm, known coronary artery calcification or metallic implants, renal insufficiency, lung disease, or allergy to contrast medium will exclude a significant percentage of patients from being candidates for CT angiography. Inasmuch as PET can be performed in a majority of these patients, and in view of the fact that revascularization improves survival over medical therapy only in patients with a moderate to severe degree of inducible ischemia, most patients will not require simultaneous assessment of coronary artery anatomy and myocardial perfusion with hybrid PET-CT. The incremental radiation dose from performing two diagnostic studies also should be taken into consideration.

Patients with low-risk stress ECG or nuclear myocardial perfusion scans show no survival advantage from revascularization over medical therapy, regardless of the angiographic extent of coronary artery stenosis (see Chapter 54). On the other hand, among younger patients with strong family history or multiple risk factors for CAD, CT angiography may not only exclude significant coronary artery luminal narrowing but also detect early atherosclerosis by quantifying the extent of calcified plaques (see Chapter 18). The latter may have important implications for aggressive risk factor modification and medical therapy. Accordingly, hybrid PET-CT should be limited to only a small subset of patients, in whom the knowledge of both coronary anatomy and physiology would be anticipated to have an impact on clinical management (e.g., anomalous coronary anatomy or myocardial bridging and chest pain).

All other applications, such as detection of endothelial dysfunction or microvascular disease and identification of soft plaques, remain experimental at this time with limited clinical data to support widespread clinical application. In the future, with the potential development of new radiotracers that target coronary artery plaque, hybrid PET-CT images that incorporate plaque anatomy with molecular imaging may provide valuable insights into differentiation of “vulnerable” from “nonvulnerable” plaque, which may be used to portend and potentially to prevent acute MIs.

Radiation Exposure Issues

Clinical decision making for the use of low-level ionizing radiation to obtain diagnostic nuclear cardiac studies must adhere to appropriate

FIGURE 16-19 Example of high-quality stress (top) and rest (bottom) PET perfusion images, using ^{82}Rb as the perfusion tracer in the short axis (SA), vertical long axis (VLA), and horizontal long axis (HLA).

FIGURE 16-20 Combined PET images of stress and rest perfusion (left) and cardiac CT angiography and calcium imaging (right). The PET images demonstrate a lateral wall reversible defect consistent with ischemia (arrows in the short-axis [SA] and horizontal long-axis [HLA] images). However, the CT images demonstrate more extensive calcification and stenosis of the left main (LM), left anterior descending (LAD), and left circumflex (LCx) vessels. The combined information suggests that although the physiologic ischemia predominantly involves the lateral wall–LCx territory, more extensive CAD is present. Red lines represent planes for cross-sectional views of coronary arteries, not shown. VLA = vertical-long axis [view].

use criteria and encompass the broad range of the risk-benefit ratio, with the guiding principle to minimize exposure while obtaining the necessary high-quality diagnostic information. The prediction of risk of subsequent malignant transformation for an individual undergoing a medical diagnostic test, or procedure, employing ionizing radiation is a complex exercise with many uncertainties. Concerns about the late carcinogenic effects of exposure to low levels (i.e., <100 mSv) of ionizing radiation stem from extrapolation of exposure outcome data in survivors of atomic bomb explosions. Uncertainty remains, however, regarding the dose-response relationship in the lower range of exposure, adding complexity to assessment of the incremental risk to subjects, as well as of tissue-specific reparative responses that also may be manifested at lower levels of exposure.²⁰ Nonetheless, exposure of the patient to ionizing radiation should be at the minimum dose consistent with obtaining a diagnostic examination. Each procedure is unique, and the methodology to achieve minimum exposure while maintaining diagnostic accuracy needs to be viewed in this light to ensure optimal patient care.

MYOCARDIAL BLOOD FLOW, MYOCARDIAL METABOLISM, AND VENTRICULAR FUNCTION

Assessment of Myocardial Blood Flow Myocardial Blood Flow at Rest

Myocardial blood flow at rest is tightly regulated to provide nutritive perfusion to viable, contractile myocytes (see Chapter 49). Although SPECT tracers to image myocardial blood flow are commonly referred to as perfusion tracers, they require viable myocyte cell membranes for uptake and retention.⁶ Thus the uptake and retention of these tracers do reflect regional flow differences, but myocyte cell membrane integrity also is a prerequisite. Visualization of myocardial regions suggests the presence of working, viable cell membranes, but lack of visualization of myocardium does not necessarily indicate the absence of viable cells. Decreased regional myocardial tracer uptake at rest could reflect either lack of cell membrane integrity in an area of infarcted myocardium or reduced blood flow secondary to hibernating but viable myocardium. A severe reduction in tracer activity usually signifies infarction, but a more moderate reduction in regional activity of a blood flow tracer alone cannot always differentiate hibernating from partially scarred myocardium in patients with ischemic LV dysfunction. In that setting, techniques that assess intact cellular metabolic processes (e.g., FDG) or the myocardial potassium space (e.g., ²⁰¹Tl redistribution) may be used as an adjunct to myocardial blood flow at rest.⁶

Imaging of Myocardial Infarction. In patients with previous MI, blood flow to the infarcted region usually is diminished, often severely, and few viable myocytes are present within the scarred territory.⁶ Thus severely reduced uptake of a radionuclide perfusion tracer in a

FIGURE 16-21 SPECT perfusion images demonstrating myocardial infarction in different locations. **A**, An apical infarction (arrows) in the horizontal long-axis (HLA) and vertical long-axis (VLA) views. **B**, An inferior infarction (arrows) in the short-axis (SA) and VLA views. In both studies, the severity of the defect suggests minimal myocyte viability within those territories.

rest study is a good marker of presence, location, and extent of MI (Fig. 16-21).

Assessment of Infarct Size. Contemporary studies have used ^{99m}Tc-sestamibi to provide an assessment of infarct size.²¹ Because clearance from the myocardium after initial uptake of this tracer is minimal, images acquired even hours after initial injection represent a “snapshot” of blood flow conditions and tracer uptake at the time of injection.

Infarct size as assessed by quantitative analysis of rest sestamibi uptake has been validated against many other measures of infarct size.²¹ Moreover, a significant association between SPECT infarct size and death occurring during long-term follow-up has been demonstrated. Many clinical trials now use “final infarct size” as determined by sestamibi SPECT imaging as an early post-MI surrogate endpoint to assess new agents to reduce infarct size.

When a tracer such as sestamibi is injected during acute MI in the setting of an occluded infarct-related artery before reperfusion therapy, the resulting defect, even when it is imaged hours later after successful reperfusion, represents the area-at-risk of the occluded artery.²¹ A second injection of sestamibi at rest with subsequent imaging can be done at a later time during the post-MI course and represents final infarct size. The change in defect size between the initial image acquired in the acute stage and the later image represents the magnitude of salvaged myocardium from reperfusion. Hence SPECT imaging at rest in the early postinfarction period can provide important information about final infarct size and infarct zone viability.

Assessment of Myocardial Perfusion During Stress

Coronary blood flow must respond rapidly to changing metabolic conditions and oxygen demand to meet the nutrient needs of myocytes being called on to contract more quickly and with more force. Oxygen extraction by the myocardium is nearly maximum at rest; thus, any increase in oxygen demand can be met only through increasing coronary blood flow to deliver more oxygen per unit time (see Chapter 49). The major determinants of coronary blood flow include the perfusion pressure at the head of the system (principally aortic diastolic pressure) and the downstream resistance, residing predominantly in the coronary arteriolar bed. Because aortic diastolic pressure during exercise varies little from the value at rest, the major mechanism responsible for increasing coronary blood flow during stress involves a reduction in coronary vascular resistance. During exercise stress, coronary blood flow can increase approximately two to three times above levels at rest. During pharmacologic stress to minimize coronary arteriolar resistance, using intravenous coronary arteriolar vasodilator agents such as dipyridamole and adenosine (discussed later), coronary blood flow can increase up to four to five times above rest levels. The magnitude of blood flow increase secondary to any stress relative to flow values at rest is termed *coronary blood flow reserve*.²²

Perfusion Tracers and Coronary Blood Flow Reserve

The ideal perfusion tracer should track myocardial blood flow across the entire physiologically relevant range of blood flow achievable in animal models and in humans (Fig. 16-22). It should be extracted rapidly (from the blood into the myocyte), because the hemodynamic conditions during peak stress are not maintained for long periods. The ideal tracer also should be extracted as completely as possible out of the bloodstream, and it should be retained in myocardium for a sufficient period to be imaged. Moreover, perturbations in metabolic conditions, such as ischemia or commonly used cardioactive drugs, should neither influence nor interfere with uptake so that the resulting regional tracer concentrations primarily reflect myocardial perfusion.⁶

Despite its excellent first-pass myocardial extraction (85%), the energy spectrum of ²⁰¹Tl is lower (69 to 80 keV) than optimum for current gamma cameras. The 140-keV energy spectrum of ^{99m}Tc perfusion tracers results in less scatter and soft tissue attenuation, with improved spatial resolution compared with thallium.⁶ However, the first-pass myocardial extraction of both sestamibi and tetrofosmin is only in the 60% range with nonlinear extraction at high flows. Thus none of the clinically available SPECT perfusion tracers have all of the properties of an ideal perfusion tracer (see Fig. 16-22).

FIGURE 16-22 The relation between myocardial blood flow and perfusion tracer uptake. The ideal perfusion tracer would track myocardial blood flow across the entire range of physiologically relevant flows (red line). However, the available perfusion tracers “roll off” at higher levels of flow. The different tracers reach a plateau at different levels of myocardial blood flow, as demonstrated in this schematic example based on multiple studies in animal models.

Nonetheless, regional differences in myocardial tracer uptake during exercise or pharmacologic stress have provided important diagnostic as well as prognostic information.⁸

The PET perfusion tracer ¹³N-ammonia displays an extraction fraction exceeding 90%; ⁸²Rb has a lower extraction fraction and reaches a plateau more rapidly at hyperemic range of flow. In the clinical setting, the evaluation of regional myocardial blood flow and flow reserve with ¹³N-ammonia and ⁸²Rb has been validated for detection and localization of CAD.¹⁵ As noted previously, most PET studies evaluating coronary flow reserve use pharmacologic rather than exercise stress.

Effect of a Coronary Stenosis on Coronary Blood Flow Reserve. In animal models in which discrete coronary stenoses of varying degrees are induced, coronary blood flow at rest is maintained by autoregulatory dilation of the downstream arteriolar resistance vessels until a stenosis between 80% and 90% of vessel diameter is reached (Fig. 16-23). As stenosis severity increases further, the arteriolar vasodilatory capacity to maintain flow at rest is exhausted, at which point coronary blood flow at rest diminishes (see Chapter 49).

By contrast, maximum coronary blood flow reserve begins to decrease when the upstream coronary stenosis reaches 50% diameter (see Fig. 49-12). Three levels of resistance influence coronary blood flow: that provided by the large-conductance epicardial vessels, designated R1; the coronary arteriolar resistance, R2; and the resistance in the subendocardium by wall tension from the ventricular chamber, R3 (see Fig. 16-23; see also Fig. 49-5). Under normal conditions, most of the resistance at rest is provided by R2, and most of the increase in coronary flow during heightened demand occurs through reduction of resistance at this level, potentially increasing flow as much as four times as demand increases. Normal epicardial vessels dilate slightly (R1 decreases slightly) in response to increased coronary flow as a consequence of normal endothelial cell function. Depending on the type of exercise that is performed, the R3 component may remain unchanged or may increase, with an increase in chamber radius and wall tension. Achieving maximal flow is predominantly dependent on the vasodilatory capacity of the downstream resistance vessels.²² With a coronary stenosis, in which some vasodilatory reserve has been used to maintain flow at rest, less vasodilatory reserve is available to minimize resistance during stress. Thus, in a vessel with a moderate stenosis, coronary blood flow reserve is blunted and detectable by a perfusion tracer (see Fig. 16-23).

In contrast with animal models, human atherosclerotic CAD is more complex. Stenoses may not be discrete, the length and complexity of the stenosis may affect the coronary reserve, and impaired endothelial function plays a role (see Chapter 49).²³ In subjects with preserved endothelial function, the increased coronary flow during stress leads to coronary arterial and arteriolar vasodilation, contributing to maximal coronary flow reserve. Endothelial function often is abnormal, with early atherosclerosis, or risk factors for atherosclerosis, contributing to the blunting of coronary flow reserve. The development of collaterals to the distal perfusion bed of a myocardial territory with a severe upstream coronary stenosis also influences blood flow at rest and during stress.²²

With SPECT imaging, relative regional differences of tracer uptake can be detected and quantified (Fig. 16-24), whereas with PET imaging, absolute regional coronary blood flow at rest and during stress (in milliliters per gram per minute) potentially can be quantified.^{6,15}

Detection of Stress-Induced Ischemia Versus Infarction

In standard practice, stress and rest myocardial perfusion images are compared to determine the presence, extent, and severity of stress-induced perfusion defects and to determine whether such defects reflect regional myocardial ischemia or infarction.^{2,7} Stress-induced perfusion abnormalities in regions that exhibit normal perfusion at rest are termed *reversible* perfusion defects, and such regions represent viable tissue with blunted coronary blood flow reserve (Fig. 16-25A; see also Figs. 16-4 through 16-7 and 16-10B). Strictly speaking, SPECT MPI demonstrates stress-induced reversible abnormalities in perfusion reserve, although these findings often are referred to as “ischemia.” Regional myocardial tissue ischemia per se is not being demonstrated, although it is indeed often present, based on a mismatch between oxygen supply and demand. Perfusion abnormalities at stress that are *irreversible*, or fixed, as seen on rest images

FIGURE 16-23 Effect of coronary resistance on coronary blood flow reserve. **A**, At rest, flow is driven by the pressure head (P) at the proximal end of the system. $R1$ refers to resistance offered by the large epicardial conductance vessels. $R2$ represents the coronary arteriolar resistance, which predominantly regulates coronary blood flow. $R3$ represents the resistance provided by wall tension in the subendocardium. At rest in the normal vessel (*left vessel* on the drawing), some vasoconstrictor resistance is present. In the setting of an epicardial coronary stenosis (*right vessel*), blood flow at rest can be maintained, but at the expense of lowering of coronary resistance downstream ($R2$ decreased) by autoregulatory dilation of the arterioles. Thus, with lower resistance, flow at rest may be maintained despite the lower pressure head at the distal end of the stenosis. A perfusion tracer would show homogeneous uptake at rest. **B**, With demand stress or with administration of a coronary arteriolar vasodilator such as dipyridamole or adenosine, perfusion increases substantially in the area supplied by the normal epicardial artery (*left vessel* on the drawing) as resistance ($R2$) becomes minimal. However, blunted flow reserve is seen in the area supplied by the stenosis (*right vessel*), because most of the vasodilator reserve at the $R2$ level has been used to maintain flow at rest. Thus heterogeneity of flow is established (based on the presence of the upstream stenosis) and can be imaged with a perfusion tracer as a defect in the territory supplied by the stenotic vessel. (Modified from Follansbee WP: *Alternatives to leg exercise in the evaluation of patients with coronary artery disease: Functional and pharmacologic stress modalities*. In Gerson MC [ed]: *Cardiac Nuclear Medicine*. New York, McGraw-Hill, 1997, pp 193-236.)

FIGURE 16-24 Graphs illustrating effect of coronary artery blood flow reserve abnormalities on perfusion tracer concentrations, with corresponding tomographic images. **Left**, The myocardial blood flow profiles at rest and stress of two myocardial regions are shown, with region S (septum) supplied by a normal epicardial artery and region L (lateral wall) supplied by an artery with a significant epicardial coronary stenosis. Blood flow at stress is diminished in region L compared with S. **Right**, The perfusion tracer uptake profile is demonstrated with myocardial blood flow on the y axis. Tracer uptake is diminished in region L relative to S during stress. In the resulting perfusion images, a relative “defect” of tracer uptake is seen in the lateral wall compared with the septum, whereas both regions demonstrate similar tracer uptake at rest. The lateral wall thus demonstrates a reversible perfusion defect, reflecting the blunted coronary blood flow reserve and indirectly reflecting the presence of the coronary stenosis.

FIGURE 16-25 **A**, Example of SPECT anterior and apical reversible perfusion defects (arrows), representing inducible regional myocardial ischemia in short-axis (SA), vertical long-axis (VLA), and horizontal long-axis (HLA) views. **B**, Example of irreversible or fixed defects of the inferolateral wall on the SA images and of the apex on the VLA images (arrows), representing predominant myocardial infarction. On the HLA image, evidence of a reversible lateral wall defect (arrows) representing lateral wall ischemia also is seen.

(unchanged from stress to rest) most often represent infarction, particularly if the defect is severe (Fig. 16-25B; see also Fig. 16-7B). When both viable myocardium and scarred myocardium are present, thallium redistribution or ^{99m}Tc tracer reversibility is incomplete, giving the appearance of partial reversibility on the delayed thallium or rest ^{99m}Tc images.

Exercise Stress to Induce Coronary Hyperemia

SPECT MPI commonly is performed with exercise stress to induce coronary hyperemia, particularly suitable for patients with exertional symptoms, because this provides the opportunity to link the symptoms induced during exercise to the location, extent, and severity of abnormal perfusion patterns.⁷ Moreover, performing exercise stress in conjunction with MPI allows the opportunity to incorporate additional information on functional capacity, stress-induced electrocardiographic changes or arrhythmias, and use of heart rate reserve and heart rate recovery in the assessment of CAD probability or prognosis (see Chapter 13).²⁴

Pharmacologic Stress to Induce Coronary Hyperemia

Exercise stress is the preferred modality to induce coronary hyperemia because it allows a correlation between exertional symptoms and the perfusion pattern and provides information on exercise duration, workload achieved, and presence and extent of ischemic electrocardiographic changes, all of which provide important diagnostic and prognostic information.²⁵ A substantial proportion of patients, however, are incapable of attaining a sufficient level of exercise. Patients with exertional symptoms may not exercise adequately to reproduce these symptoms, and patients may not achieve more than 85% of the maximum predicted heart rate for age (see Chapter 13), considered the optimal level of exertion to achieve coronary hyperemic responses.^{7,24} As the population ages and the prevalence of comorbid disease states such as peripheral vascular disease and diabetes increases, the proportion of patients referred for stress testing who are unable to achieve adequate levels of exercise will increase.

In such patients, pharmacologic stress testing can be used to induce coronary hyperemia. The most widely used agents for pharmacologic stress testing can be divided into those that act as coronary arteriolar vasodilators (adenosine, dipyridamole, and regadenoson) and adrenergic agents such as dobutamine.^{7,25}

Mechanism of Coronary Arteriolar Vasodilator Pharmacologic Stress

Stimulation of adenosine A_{2a} receptors on the smooth muscle cells leads to enhanced production of adenylate cyclase, increased intracellular cyclic adenosine monophosphate, and other effects that produce vasorelaxation. With maximal arteriolar vasodilation (maximal decrease in coronary resistance), coronary blood flow increases.

Adenosine is a powerful, endogenous molecule that acts as a regulator of blood flow in many organ beds, including the coronary circulation (see Chapter 49). It has many other effects mediated by different receptor subtypes (Fig. 16-26). Adenosine A_1 receptors are present in the sinus node and atrioventricular (AV) node and mediate diminished heart rate and AV nodal conduction. Adenosine A_{2b} receptors are present in bronchioles and the peripheral vasculature, and stimulation may result in bronchial constriction and peripheral vasodilation.

Initial studies of adenosine demonstrated that a dose of 140 $\mu\text{g}/\text{kg}/\text{min}$ induced maximal coronary hyperemia, with no further increase in maximum coronary blood flow at higher doses.²⁵

After the onset of intravenous adenosine infusion, maximum coronary flow occurs at an average of 84 seconds, with a range of up to 125 seconds. Dipyridamole blocks the intracellular retransport of adenosine and inhibits adenosine deaminase, responsible for the intracellular breakdown of adenosine.²⁵ Thus dipyridamole acts as an indirect coronary arteriolar vasodilator, increasing intracellular and interstitial concentrations of adenosine (see Fig. 16-26). The newer agent regadenoson is similar to adenosine in that it directly interacts with the adenosine A_{2a} receptor.²⁶

Heterogeneity of Coronary Hyperemia with Pharmacologic Stress

With the administration of dipyridamole or adenosine, the resistance vessels in the area subtended by a normal epicardial vessel dilate, diminishing coronary resistance and resulting in an increment in coronary blood flow four to five times above normal. Coronary resistance in a bed supplied by a stenotic epicardial vessel is diminished at rest (i.e., coronary vasodilator reserve has been used), and only minor or no further reductions can take place. Thus myocardial blood flow in that territory does not change or may even decrease slightly because of the peripheral vasodilation and drop in diastolic blood pressure characteristic of pharmacologic stress. The net result of these changes is heterogeneity in myocardial blood flow (increased in the normal territory and relatively unchanged in the territory supplied by the stenotic epicardial vessel). Perfusion tracer

FIGURE 16-26 Schematic of the mechanism of action of dipyridamole, adenosine, and regadenoson. Exogenously administered adenosine acts directly on its receptor to result in coronary arteriolar vasodilation and a consequent increase in myocardial blood flow (MBF) as resistance is minimized. Regadenoson directly interacts with the adenosine A_{2a} receptor. The adenosine A_{2a} receptor mediates coronary arteriolar vasodilation, which is the basis for pharmacologic stress testing. Dipyridamole blocks the intracellular retransport of adenosine and also inhibits adenosine deaminase (ADA), resulting in increased intracellular and interstitial concentrations of adenosine, which then interacts with its receptor. (Modified from Follansbee WP: *Alternatives to leg exercise in the evaluation of patients with coronary artery disease: Functional and pharmacologic stress modalities*. In Gerson MC [ed]: *Cardiac Nuclear Medicine*. New York, McGraw-Hill, 1997, pp 193-236.)

administration in this setting demonstrates a defect in the area supplied by the stenotic vessel (see Fig. 16-23).²⁵

During exercise stress, the increase in myocardial oxygen demand and limitation of oxygen supply create a supply-demand mismatch often resulting in cellular ischemia. With pharmacologic stress, the perfusion defect may represent merely the heterogeneity in coronary flow reserve. "Demand" may change little during pharmacologic stress; there is often a reduction in blood pressure accompanied by a reflex although modest increase in heart rate, so that double product, reflecting oxygen demand, changes little during the vasodilator "stress." Thus a supply-demand mismatch may not occur, and cellular ischemia may not be present, despite vasodilator-induced perfusion defects.²⁵

Under certain conditions, true myocardial ischemia may indeed be present, related to development of a coronary steal. This phenomenon appears to occur when the myocardial perfusion bed supplied by a severe epicardial stenosis also is dependent on collateral vessels from remote coronary arteries. Blood flow through coronary collaterals is dependent on perfusion pressure, particularly if the collaterals are jeopardized (i.e., if the parent blood vessel is compromised by moderate coronary stenosis). In this setting, administration of a vasodilator stress agent diminishes the perfusion pressure supplying the collaterals, and collateral flow diminishes. Flow to the bed supplied by a severe epicardial stenosis may then decrease compared with flow at rest, and the diminished supply may create supply-demand mismatch and true myocardial ischemia, with ECG ST-segment depression.

Hemodynamic Effects of Vasodilator Pharmacologic Stress.

Administration of dipyridamole, adenosine, and regadenoson results in adenosine receptor-mediated systemic as well as coronary vasodilation, with an average reduction of 8 to 10 mm Hg in systolic and diastolic blood pressure, often accompanied by a reflex increase in heart rate.²⁵ The magnitude of the heart rate increase is variable, usually between 10 and 20 beats/min. A blunted heart rate response may be observed in patients who are taking beta blockers or in diabetic patients with underlying autonomic insufficiency.

Side Effects Associated with Vasodilator Pharmacologic Stress. The side effects associated with pharmacologic vasodilator stress are the result of stimulation of the adenosine A₁, A_{2b}, and A₃ receptors and are common.²⁵ After dipyridamole stress, approximately 50% of patients experience some side effect, and with adenosine more than 80% of patients experience untoward side effects, most commonly flushing, chest pain, or shortness of breath.^{2,25} In the pivotal clinical trials of regadenoson, the prevalence of side effects was similar to that seen with adenosine, though a composite severity score was slightly lower.²⁶

As a result of adenosine's effect on the conduction system, AV block may develop during adenosine administration. Approximately 10% of patients manifest first-degree AV block, with 5% developing either second- or third-degree AV block. AV block is more common in patients who are studied while they are taking beta blockers or heart rate-lowering calcium channel blockers. Patients with baseline evidence of second- or third-degree AV block in the absence of a pacemaker should not receive adenosine. However, patients with first-degree AV block or left bundle branch block (LBBB) appear to tolerate adenosine infusion well, without an exacerbation of conduction abnormalities.^{2,7,25}

Ischemic ST depression is observed in 10% to 15% of patients undergoing pharmacologic vasodilator stress, probably representing the physiologic consequence of induction of a coronary steal and regional myocardial ischemia. Such patients often have extensive and severe perfusion defects on imaging and more often have collateralized multivessel disease on angiography.

Chest pain, even typical angina pectoris, develops commonly during pharmacologic vasodilator stress testing. Although it may reflect regional myocardial ischemia based on a coronary steal, chest pain also may occur in patients with no ischemic ECG changes and with normal perfusion studies because of involvement of adenosine A₁ receptors in the nociceptive pathway influencing the sensation of chest pain.²⁵ Thus chest pain by itself is a nonspecific finding during vasodilator pharmacologic stress.

In early reports of dipyridamole testing, infrequent but severe episodes of bronchospasm occurred, possibly related to a nonspecific adenosine receptor-mediated mechanism. Thus patients with a

significant history of reactive airways disease should not undergo vasodilator stress testing.^{2,7,25} Patients with chronic obstructive pulmonary disease (COPD) without a reactive airways component, however, generally tolerate the procedure well. Regadenoson has been studied in patients with mild to moderate asthma and in patients with moderate COPD. In a randomized trial, the incidence of a greater than 15% decrement in forced expiratory volume in 1 second (FEV₁) from baseline was similar in regadenoson- and placebo-treated patients, although dyspnea was more common in the regadenoson-treated patients.²⁷ No cases of severe bronchospasm occurred. These data suggest that regadenoson may be used in such patients, albeit with caution and after preparation to treat dyspnea.

Vasodilator pharmacologic stress agents have been under development that are more specific agonists at the adenosine A_{2a} receptor in receptor model systems. One of these agents, regadenoson, discussed earlier, was approved by the FDA in 2008 for use in pharmacologic stress testing for MPI, and is now widely used. Pivotal trials suggested imaging performance similar to that of adenosine. The overall side effect profile does not appear to be very clearly different from that of adenosine. Regadenoson is administered as a bolus, however, which is more convenient than with the other vasodilator stress agents in use.^{25,26}

Reversal of the Effects of Vasodilator Pharmacologic Stress.

Methylxanthine compounds such as theophylline and caffeine act as competitive antagonists of adenosine at the receptor level, and infusion of intravenous aminophylline antagonizes the effects of the vasodilator stress agents.^{2,7} Because adenosine has a very short half-life (approximately 20 to 30 seconds), administration of aminophylline is rarely required during adenosine testing; simply stopping the infusion results in cessation of symptoms within 20 to 30 seconds. After intravenous dipyridamole or regadenoson, infusion of aminophylline at approximately 1 to 2 mg/kg, given during 30 seconds, reverses side effects (as well as the coronary vasodilator effects), usually within 1 to 2 minutes. Because the coronary vasodilator effects will be reversed as well, reversal of the vasodilator effect should be delayed until at least 1 to 2 minutes after radionuclide administration if it is clinically safe; otherwise, the true stress perfusion pattern may not be evident. In general, side effects from vasodilator pharmacologic stress, although common, may be tolerated for this time. However, with more severe side effects, such as severe shortness of breath or bronchospasm, or with more dramatic ST-segment abnormalities, reversal of the vasodilator effect more quickly is prudent. Because caffeine is a methylxanthine compound and antagonizes the effect of adenosine at its receptor, it is critical that patients be instructed to withhold caffeine, ideally for 24 hours before vasodilator pharmacologic stress testing.

In some patients, myocardial ischemia provoked during vasodilator stress testing triggers a cascade of events that maintains ischemia even after reversal of the vasodilator effect with aminophylline. The sensation of chest pain may drive a heightened sympathetic response, with an elevation of heart rate and blood pressure. In that setting, when aminophylline has been given to reverse the effects of the vasodilator, it is safe to administer sublingual nitroglycerin or other measures to relieve myocardial ischemia. It is not safe to give sublingual nitroglycerin before aminophylline to treat signs of myocardial ischemia. Because systemic vasodilation is present during vasodilator stress testing, administration of nitroglycerin before aminophylline may result in substantial systemic hypotension.

In contemporary practice, a small number of patients may be encountered who are taking oral dipyridamole preparations for their antiplatelet effects. Because dipyridamole is an adenosine deaminase inhibitor and prevents the usual rapid breakdown of adenosine, infusion of intravenous adenosine in patients receiving oral dipyridamole may be accompanied by a far more prolonged adenosine effect than usual. For adenosine testing, therefore, oral dipyridamole compounds must be stopped at an appropriate time before the procedure. Similar precautions apply to the use of regadenoson in patients receiving oral dipyridamole. Oral dipyridamole as background therapy does not complicate the performance of intravenous dipyridamole testing.

Protocols for Vasodilator Pharmacologic Stress Testing

The accepted protocols for performing vasodilator pharmacologic stress testing are listed in Table 16-3.^{2,7,25} Since the original descriptions of these protocols, iterations have been studied, with the goal of shortening the test procedure or minimizing side effects, or both,²⁵ by shortening the duration of the adenosine infusion or adding low-level exercise.

TABLE 16-3 Pharmacologic Stress Protocols

AGENT	DOSE	DURATION	ISOTOPE INJECTION
Dipyridamole	142 µg/kg/min	4 minutes by hand infusion or pump	3 minutes after completion of infusion
Adenosine	140 µg/kg/min	6-minute infusion by pump	At 3 minutes into infusion
Regadenoson	0.4 mg (5 mL) rapid IV injection, followed by 5 mL saline flush	Bolus	10-20 seconds after the saline flush

Handgrip exercise may be used to raise peripheral blood pressure and thus coronary perfusion pressure. Reports are mixed on whether image quality is improved. This approach may be useful in patients with borderline low blood pressure before the test to avoid significant hypotension.

Low-level treadmill exercise has been increasingly applied in combination with vasodilator stress testing. Although no clear advantage in diagnostic performance has been shown, a reduction in side effects of pharmacologic stress testing has been consistently demonstrated, as well as a reduction in extracardiac tracer uptake with consequent improvement in image quality.²⁵

Initial reports of intravenous adenosine testing described a protocol in which the dose was progressively increased. More commonly, adenosine is given as an infusion starting with the maximum dose. This protocol allows a shortened total infusion period of 4 minutes rather than 6 minutes, with radionuclide injected at 3 minutes into the 4-minute infusion. Published data suggest that diagnostic sensitivity is maintained while the overall time of testing is decreased.²⁵

Differences Between Vasodilator and Exercise Stress

The perfusion images obtained by vasodilator pharmacologic stress generally are concordant with those obtained with maximal exercise stress in the same patient, but with several important differences: Higher levels of coronary flow are achieved during vasodilator pharmacologic stress compared with exercise, possibly because of the increased resistance to flow with exercise caused by higher subendocardial pressures. Although theoretically this difference should result in increased sensitivity for detection of CAD with pharmacologic stress, such heightened sensitivity has not been clearly demonstrated. The failure to demonstrate increased sensitivity may be due to the inability of the radionuclide tracers to reflect myocardial blood flow adequately at the highest levels of flow (see Fig. 16-22).⁶

Vasodilator pharmacologic stress is less “physiologic” than exercise, and symptoms during testing (or lack thereof) cannot be as clearly linked to the perfusion pattern. Optimal diagnostic performance of MPI during exercise often is dependent on the patient’s achieving a maximal level of stress, which does not always occur.

Anti-ischemic medications may significantly affect the results of MPI during exercise.⁷ The extent and severity of myocardial perfusion defects also may be affected in an important way by background medication during pharmacologic stress.²⁸ Antianginal medications should therefore be withheld if possible before the study.

Dobutamine Stress to Induce Coronary Hyperemia. In some patients, vasodilator pharmacologic stress is contraindicated because of reactive bronchospastic airways disease or background methylxanthines. In such cases, intravenous dobutamine hydrochloride may be used to induce coronary hyperemia.^{2,7} Dobutamine has a relatively rapid onset of action, with a half-life of approximately 2 minutes. This agent is given starting at a dose of 5 µg/kg/min and increased in a stepwise fashion by 5 µg/kg/min every 3 minutes, to a maximum dose of 40 µg/kg/min (see Chapter 14). Dobutamine is a broad adrenergic receptor agonist, at varying doses stimulating the beta₁, beta₂, and alpha₁ receptors. At relatively low doses, the predominant effect is an

increase in contractility mediated through adrenergic receptors. As the dose is increased beyond 10 µg/kg/min, heart rate rises steadily, and the increase in oxygen demand stimulates an increase in myocardial blood flow.

The hemodynamic response to dobutamine generally involves a modest increase in systolic blood pressure with a modest decrease in diastolic blood pressure through doses up to 20 µg/kg/min, with only small further changes after that point. Because the increase in myocardial blood flow is dependent on the increase in oxygen demand, optimal sensitivity for MPI based on optimizing heterogeneity of flow is dependent on achieving an adequate heart rate response, often requiring a high dose of dobutamine.

The increment in myocardial blood flow during maximal doses of dobutamine appears to be less than that achieved during vasodilator pharmacologic stress, so the degree of heterogeneity of coronary flow with a coronary stenosis also is less. Thus vasodilator stress is the preferred pharmacologic modality for MPI in patients who cannot exercise adequately. Dobutamine stress is reserved for cases in which vasodilator stress is contraindicated or cannot be performed because of background medications.^{2,7,25}

Side effects of dobutamine are frequent and can be bothersome.² The most common side effects include palpitations and chest pain, and arrhythmias including PVCs and nonsustained ventricular tachycardia may be encountered. Hypotension occurs in approximately 10% of patients, possibly as a result of myocardial mechanoreceptor stimulation during increased contractility with resulting withdrawal of peripheral constrictor tone. Hypotension during dobutamine stress does not have the same prognostic implications as exercise-induced hypotension. Because of the relatively short half-life, side effects generally resolve within a few minutes of stopping the infusion and can be aborted more quickly with intravenous beta-adrenergic blockade.^{2,7,25}

Assessment of Myocardial Cellular Metabolism and Physiology

Myocardial Ischemia and Viability

Programmed Cell Survival

Imbalance between oxygen supply and demand results in myocardial ischemia. If the imbalance is transient (i.e., triggered by exertion), it represents reversible ischemia. However, if supply-demand imbalance is prolonged, high-energy phosphates are depleted, and regional contractile function progressively deteriorates. If the supply-demand balance is sufficiently prolonged, cell membrane rupture with cell death follows.

The myocardium has several mechanisms of acute and chronic adaptation to a temporary or sustained reduction in coronary blood flow (Fig. 16-27), known as stunning, hibernation, and ischemic preconditioning (see Chapter 49). These responses to ischemia preserve sufficient energy to protect the structural and functional integrity of the cardiac myocyte. In contrast with programmed cell death, or *apoptosis*, the term *programmed cell survival* has been used to describe the commonality between myocardial stunning, hibernation, and ischemic preconditioning despite their distinct pathophysiology.²⁹

Stunned and Hibernating Myocardium

In stunned and hibernating myocardium, myocardial function is depressed at rest, but myocytes remain viable. Although LV dysfunction may be reversible in both stunning and hibernation, these states differ in the relationship between myocardial perfusion and function. Stunned myocardium is most commonly observed after a transient period of ischemia followed by reperfusion (depressed function at rest but preserved perfusion). The ischemic episodes can be single or multiple, brief or prolonged, but never severe enough to result in injury. Hibernating myocardium refers to adaptive responses of the myocardium to repetitive episodes of ischemia resulting in myocardial hypoperfusion at rest³⁰ (depressed function and perfusion at rest). In clinical practice, it is likely that the adaptive responses of hibernation and stunning coexist (see Chapter 49).

Myocardial Viability

Requirements for cellular viability include (1) sufficient myocardial blood flow, (2) cell membrane integrity, and (3) preserved

FIGURE 16-27 Pathophysiology of stunning (**A**) and hibernation (**B**), representing different mechanisms of acute and chronic reversible left ventricular dysfunction. (Modified from Dilsizian V: Myocardial viability: Reversible left ventricular dysfunction. In Dilsizian V, Narula J, Braunwald E [eds]: *Atlas of Nuclear Cardiology*. Philadelphia, Current Medicine, 2006.)

metabolic activity. Myocardial blood flow has to be adequate to deliver substrate to the myocyte for metabolic processes and to remove the end products of metabolism. If blood flow is severely reduced, metabolites accumulate, causing inhibition of the enzymes of the metabolic pathway, depletion of high-energy phosphates, cell membrane disruption, and cell death. Thus, with severe

reduction in blood flow, perfusion tracers alone provide information about myocardial viability.⁶ However, in regions in which the reduction in blood flow is less severe, perfusion information alone may be an insufficient signal to identify clinically relevant viability, and additional data, such as metabolic indices, would be important.⁶

Because cell membrane integrity, another requisite for cell survival, is dependent on preserved intracellular metabolic activity to generate high-energy phosphates, tracers that reflect cation flux (^{201}Tl), electrochemical gradients (sestamibi or tetrofosmin), or metabolic processes (FDG) provide insight into myocardial viability^{6,30} (Fig. 16-28).

Major Myocardial Fuels and Energetics in Normal and Ischemic Myocardium

High-energy phosphates, such as adenosine triphosphate (ATP), provide the fuel that powers the myocyte contractile proteins (see Chapter 22). ATP is generated in the myocardium by two different but integrated metabolic processes: oxidative phosphorylation and

FIGURE 16-28 **A**, Mechanisms of uptake and retention of ^{201}Tl and $^{99\text{m}}\text{Tc}$ perfusion tracers. **B**, Mechanism of uptake and retention of PET agents tracing perfusion (^{82}Rb) and oxidative and anaerobic metabolism (^{11}C -acetate, ^{11}C -palmitate, and ^{18}F -deoxyglucose). ADP = adenosine diphosphate; ATP = adenosine triphosphate; CoA = coenzyme A; FA = fatty acid; Glucose-6-P = glucose-6-phosphate. (Modified from Dilsizian V: *SPECT and PET techniques*. In Dilsizian V, Narula J, Braunwald E [eds]: *Atlas of Nuclear Cardiology*. Philadelphia, Current Medicine, 2006.)

glycolysis.^{15,29} Fatty acids, glucose, and lactate are the major sources of energy in the heart, and depending on the arterial concentration of each and the physiologic condition, any one of these three can be the principal substrate (Fig. 16-28B).²⁹ Increased uptake and use of one substrate will lead to a decreased contribution by the others.

In the fasting state, long-chain free fatty acids are the preferred source of energy in the heart, with glucose accounting for only 15% to 20% of the total energy supply. When the oxygen supply is normal, high levels of ATP and tissue citrate formed by breakdown of fatty acids suppress the oxidation of glucose. When the oxygen supply is decreased, ATP and citrate levels fall, and the rate of glycolysis is accelerated. Anaerobic glycolysis can be maintained only if lactate and hydrogen ion (the byproducts of glycolysis) are removed and do not accumulate. In the setting of severe hypoperfusion, these end products of the glycolytic pathway accumulate, causing inhibition of the glycolytic enzymes and depletion of high-energy phosphates, resulting in cell membrane disruption and cell death.²⁹ Thus, even to maintain anaerobic glycolysis, minimally sufficient blood flow is necessary.

Imaging of Alterations in Myocardial Metabolism

Imaging of Fatty Acid Metabolism. Because fatty acids are the primary source of myocardial energy production in the fasting state, early PET studies focused on characterizing the kinetics of long-chain fatty acids, such as ¹¹C-palmitate.³⁰

¹¹C-palmitate: Measurement by dynamic PET imaging allows determination of tracer inflow (by regional perfusion), peak accumulation, and release within a region of interest. Once the tracer is in the cell, it either (1) enters the endogenous lipid pool or (2) moves to the mitochondria, where rapid degradation by beta oxidation results in the generation of carbon dioxide. Depending on demand, approximately 80% of extracted ¹¹C-palmitate is activated for transport from the lipid pool into the mitochondria for breakdown by beta oxidation. Because of its complicated kinetic modeling and numerous confounding effects, ¹¹C-palmitate imaging has not gained wide clinical acceptance.

¹²³I-BMIPP: Fatty acid imaging with radioiodine-labeled fatty acid analogues, such as iodine-123–labeled beta-methyliodopentadecanoic acid (BMIPP) with SPECT, is an investigational area for the assessment of ischemic memory.³¹ After an ischemic episode, fatty acid metabolism may be suppressed for a prolonged period, and BMIPP imaging can demonstrate a regional metabolic defect even if perfusion has returned to normal. This metabolic signal of recent ischemia has been termed ischemic memory and may be clinically useful, for example, in patients who report to an emergency department (ED) with chest pain that resolved hours earlier. Although BMIPP is approved for clinical use in Japan, it has not yet received approval by the FDA.

Imaging of Glucose Metabolism. Although fatty acids are the primary source of fuel in the fasting state, increased arterial glucose concentration in the fed state results in an increase in insulin levels, stimulating glucose metabolism while inhibiting lipolysis.^{6,15,29} The result is a switch in myocardial metabolism from predominant use of fatty acids to glucose.

The principle of using a metabolic tracer that tracks glycolysis is based on the concept that glucose utilization may be preserved or increased relative to flow in hypoperfused but viable (hibernating) myocardium, termed metabolism-perfusion mismatch.^{6,15,29} Myocardial glucose use is absent in scarred or fibrotic tissue, represented by metabolism-perfusion match (Fig. 16-29). Although the amount of energy produced by glycolysis may be adequate to maintain myocyte viability and to preserve the electrochemical gradient across the cell membrane, it may not be sufficient to sustain contractile function.²⁹

²⁻¹⁸F-fluoro-2-deoxyglucose: FDG is a glucose analogue used to image myocardial glucose use with PET.^{6,15,29} After injection of 5 to 10 mCi, FDG rapidly exchanges across the capillary and cellular

FIGURE 16-29 Assessment of viability by PET imaging. **Top row,** ⁸²Rb is used as a tracer of myocardial blood flow at rest in these short-axis images starting toward the apex (left) and moving toward the base of the heart (right). Myocardial perfusion is markedly decreased in the apical, inferior, inferolateral, and septal regions. **Bottom row,** ¹⁸F-fluorodeoxyglucose (FDG) is used as a tracer of myocardial glucose metabolism. FDG uptake is enhanced relative to blood flow, demonstrating a pattern of perfusion-metabolism mismatch in most abnormally perfused myocardial regions, indicative of viable or hibernating myocardium. An exception is the anteroapical region, which demonstrates a matched perfusion-metabolism pattern, indicative of nonviable or scarred myocardium. (From Taegtmeyer H, Dilsizian V: *Imaging myocardial metabolism and ischemic memory*. *Nat Clin Pract Cardiovasc Med* 5[Suppl 2]:S42, 2008.)

membranes. It is phosphorylated by hexokinase to FDG-6-phosphate (see Fig. 16-28B) and not metabolized further or used in glycogen synthesis. Because the dephosphorylation rate of FDG is slow, it becomes trapped in the myocardium, permitting PET or SPECT imaging of regional glucose use. FDG uptake may be increased in dysfunctional but viable myocardium, and FDG uptake in asynergic myocardial regions with reduced blood flow at rest has become a scintigraphic marker of hibernation.

Diagnostic quality of FDG imaging is critically dependent on hormonal milieu and substrate availability. Most clinical FDG studies are performed after 50 to 75 g of glucose loading in the form of oral dextrose approximately 1 to 2 hours before the FDG injection to increase glucose metabolism, to maximize FDG uptake, and to improve image quality.^{6,15,29} Although 90% of FDG images are of diagnostic quality in nondiabetic patients, the quality of FDG images after glucose loading alone is less certain in patients with clinical or subclinical diabetes, because the increase in plasma insulin levels may be attenuated, tissue lipolysis may not be inhibited, and free fatty acid levels may remain high. Standardization schemes to optimize FDG image quality in diabetic patients include (1) intravenous insulin injections after glucose loading, (2) hyperinsulinemic-euglycemic clamping, and (3) use of nicotinic acid derivative.^{6,15}

Imaging of Oxidative Metabolism and Mitochondrial Function. **¹¹C-acetate:** All oxidative fuels are metabolized in the tricarboxylic acid cycle after conversion to acetyl coenzyme A. ¹¹C-acetate is avidly extracted by the myocardium and metabolized predominantly by conversion to ¹¹C-acetyl coenzyme A in the cytosol and by oxidation via the tricarboxylic acid cycle in the mitochondria to ¹¹C-carbon dioxide and water. Hence the rapid myocardial turnover and clearance of ¹¹C-acetate in the form of ¹¹C-carbon dioxide may reflect myocardial oxidative metabolism and provide insight into mitochondrial function.⁶ In patients with recent MI and chronic stable angina, clearance rates of ¹¹C-acetate predict myocardial viability and functional recovery after revascularization. Despite encouraging data in the literature, ¹¹C-acetate remains an investigational tracer.

Assessment of Ventricular Function

Left Ventricular Systolic Function

The EF as an index of global systolic LV performance is influenced by many factors, including the intrinsic state of contractility, preload, and afterload as well as neurohormonal and inotropic influences (see Chapter 21). Despite its load dependence, EF has proved to be clinically useful as a marker of LV performance. In the aftermath of acute MI, the postinfarction EF is among the most powerful indices predictive of subsequent death.^{7,32} The radionuclide techniques used to image ventricular function, including RVG, gated SPECT, and gated PET imaging, have provided substantial insight into the physiology of LV function and the response to disease states (Videos 16-1 and 16-2).

**VIDEO 16-1**

FDG PET imaging. Gated FDG PET images show severe global hypokinesis with left ventricular ejection fraction (LVEF) of only 11%.

VIDEO 16-2

Rubidium PET imaging. Rest and pharmacologic stress rubidium PET images show concentric left ventricular hypertrophy without regional perfusion defect to suggest myocardial ischemia or prior infarction. LVEF is 70% at rest and 74% during adenosine stress acquisition.

Assessing the Left Ventricular Response to Exercise

Equilibrium-gated RVG and first-pass RVG are among the few noninvasive imaging techniques that can evaluate ventricular performance during exercise.¹⁴ Most often, this is accomplished by imaging of the patient during bicycle exercise, supine or semisupine for equilibrium RVG and upright for first-pass RVG. EF measurements during exertion can then be compared with EF values at rest.¹⁴

This technique has been used to study the response of LV function and volumes to exercise. For example, in younger normal subjects, the normal increase in EF and cardiac output is accomplished by decreasing end-systolic volume. By contrast, among older normal subjects, the increase in EF and cardiac output during exercise is accomplished by increasing end-diastolic volume (using preload reserve). In healthy subjects, the normal EF response to exercise is an increase of more than five EF units. The underlying physiology of this increase changes as normal subjects age.¹⁴

The relative ease with which the EF response to exercise may be studied by RVG techniques led to many reports in the late 1970s and throughout the 1980s. However, evaluation of LV function during exercise by RVG has now been largely replaced by exercise echocardiography (see Chapter 14).

Evaluation of Left Ventricular Volumes

With the RVG technique, the counts detected from the LV region of interest are proportional to LV volume. The proportional relation can be estimated from a blood sample of known volume, in which the quantitative relationship between counts and volume can be determined after correction for attenuation.^{2,7,14}

The major advantage of the RVG technique for evaluation of ventricular volumes (and function) over contrast ventriculographic and echocardiographic methods is that the radionuclide techniques do not require assumptions about ventricular geometry. With use of RVG techniques, volumes are calculated from count rates over a region of interest involving the left or right ventricle, or both, and are based on photon emissions from the region of interest.¹⁴ Thus the radionuclide techniques are not dependent on any assumption of ventricular geometry and are suitable for the study of ventricular volumes when ventricular geometry is abnormal.

Serial studies of LV volumes have been useful in evaluating the process of LV remodeling after MI and in chronic heart failure,³³ in which a progressive increase in LV volume occurs in the absence of neurohormonal blockade. For example, serial RVG studies have shown that the effect of angiotensin-converting enzyme (ACE) inhibition is an early reduction in LV volume, which is maintained during follow-up.³³

LV volumes also may be calculated using gated SPECT perfusion imaging, and volumetric data have been validated against those obtained using other quantitative techniques.³⁴ At present, the accumulated experience with gated SPECT perfusion imaging for serial evaluation of LV volumes is less than that with equilibrium RVG volumetric techniques. Nonetheless, the ability to evaluate simultaneously LV function, perfusion, and volumes demonstrates the clinical versatility of gated SPECT MPI.

Serial Evaluation of Left Ventricular Function

The quantitative nature of radionuclide analysis of ventricular function and the high reproducibility of the measurement make ECG-gated RVG or ECG-gated SPECT imaging well suited for serial follow-up evaluation of changes in LV systolic performance. There are many clinical situations in which serial changes in LV function are clinically relevant, such as in patients with heart failure,³³ those observed with valvular heart disease,³⁵ and those receiving cardiotoxic chemotherapy (see Chapters 25, 63, and 69).³⁶ Serial RVG studies demonstrating diminution in EF suggested that the early onset of myocardial dysfunction can herald the onset of a higher-risk clinical course directing clinical management decisions.

The accuracy and reproducibility of the RVG technique for assessing LV function make this technique particularly suitable for serial follow-up assessment of patients with regurgitant valvular heart disease. In studies using RVG for ongoing monitoring, patients with

asymptomatic chronic severe aortic regurgitation who demonstrated the onset of LV dysfunction, even when they remained asymptomatic, were found to be at higher risk for adverse clinical outcomes than are those with preserved LV performance.³⁵ On the basis of such RVG data, the onset of LV dysfunction in an asymptomatic patient with aortic regurgitation is considered to be an indication for surgery. Similarly, serial RVG follow-up evaluation of patients undergoing cardiotoxic chemotherapy³⁶ has demonstrated that a decline in EF, as detected by RVG, of 10% to a final level less than 50% indicates high risk for the development of subsequent heart failure.

Evaluation of Diastolic Function. Although the most important quantitative variable derived from RVG evaluation of LV function in a majority of cardiac diseases is the EF, numerous other quantitative variables, including indices describing LV diastolic performance, also may be derived.

Left Ventricular Diastolic Filling. Radionuclide assessment of LV filling properties is based on analysis of the LV time-activity curve, usually obtained by equilibrium RVG techniques,² which represents relative volume changes throughout the cardiac cycle (Fig. e16-6). With appropriate data acquisition methods and attention to technical considerations, several parameters of diastolic function may be calculated from the time-activity curve, including the peak rate of rapid diastolic filling, the time to peak filling rate, and the relative contributions of the rapid filling period and of atrial systole to total LV stroke volume. Several studies have shown good correlation between various radionuclide and Doppler echocardiographic measures of filling, because both techniques assess physiologic events during the filling period.^{2,7}

Evaluation of Diastolic Filling by Equilibrium RVG in Disease States

Hypertrophic Cardiomyopathy. Abnormal diastolic properties of the hypertrophied ventricle are a characteristic feature of hypertrophic cardiomyopathy (HCM) (see Chapter 66), contributing notably to clinical manifestations.³⁷ Studies using RVG have demonstrated that the rate and extent of rapid filling are reduced in HCM, that the time to peak filling rate is prolonged, and that the contribution of atrial systole to total LV stroke volume is increased.³⁷

Heart Failure. Radionuclide studies have provided evidence of an abnormal end-diastolic volume response to exercise in patients with heart failure and preserved systolic performance (see Chapter 27), supporting the concept of diastolic dysfunction as an underlying cause of symptoms. Patients with heart failure but preserved systolic performance fail to increase end-diastolic volume during exercise, associated with a substantial increase in wedge pressure (Fig. e16-7). In contrast, normal subjects demonstrate an increase in end-diastolic volume associated with no change in wedge pressure, recruiting preload despite no change in left atrial driving pressure. Patients with heart failure and normal systolic performance require higher filling pressures to maintain stroke volume, at the cost of an increased pulmonary wedge pressure, contributing to dyspnea. Thus abnormal diastolic performance, manifested by an impaired ability to recruit end-diastolic volume (preload reserve), as demonstrated by equilibrium RVG, results in physiologic abnormalities leading to heart failure in these patients with normal systolic function.

DISEASE DETECTION, RISK STRATIFICATION, AND CLINICAL DECISION MAKING

Stable Chest Pain Syndromes

Application of Radionuclide Imaging: Answering the Clinical Questions

For patients with stable symptoms of suspected CAD (see Chapter 54) who are referred for noninvasive testing, the two major goals of testing are to ascertain whether CAD is present or absent—the *diagnostic construct*—and to determine the longer-term prognosis or the risk for an adverse outcome over time—the *prognostic construct*. These goals of testing are linked to the two main treatment goals for patients with suspected or known CAD: (1) amelioration of symptoms in everyday life and (2) improvement in outcome.

Establishment of the presence or absence of CAD is an important goal of testing. The performance characteristics of radionuclide imaging for this purpose often are based on an angiographic definition of stenosis of 50% or greater, or 70% stenosis in an individual

FIGURE e16-6 Quantitative analysis of systolic and diastolic events by radionuclide ventriculography. The x axis represents time across one average cardiac cycle, and the y axis represents count activity within the left ventricular region of interest, which is expressed as a percentage of end-diastolic volume (EDV %). The time-activity curve represents the relative change in volume within the ventricle during the cardiac cycle. In this high-temporal-resolution example, each point represents 20 milliseconds. Indices of diastolic function may be calculated from analysis of the filling portion of the curve, including the peak rate of rapid filling (PFR), the time from end systole at which peak filling occurs (TPFR), and the relative contribution of rapid diastolic filling (RDF) and of atrial systole (AS) to total stroke volume. (Modified from Udelson JE, Bonow RO: Radionuclide ventriculography in left ventricular diastolic dysfunction. In Gaasch WH, LeWinter M [eds]: *Heart Failure and Diastolic Dysfunction*. Philadelphia, Lea & Febiger, 1994, pp 167-191.)

FIGURE e16-7 Use of radionuclide ventriculography to evaluate changes in end-diastolic volume (EDV) during exercise. In normal subjects (*closed symbols*), there is an increase in EDV during exercise (recruitment of preload reserve) with only minor change in pulmonary capillary wedge pressure. By contrast, patients with heart failure and preserved systolic function (*open symbols*) manifest no change in EDV during exercise despite substantial increase in pulmonary capillary wedge pressure, to levels that would be associated with symptoms such as shortness of breath. (Modified from Kitzman DW, Higginbotham MB, Cobb FR, et al: *Exercise intolerance in patients with heart failure and preserved left ventricular systolic function: Failure of the Frank-Starling mechanism*. *J Am Coll Cardiol* 17:1065, 1991.)

epicardial vessel. This definition of CAD is based in part on seminal studies in animal models showing that a 50% stenosis begins to blunt coronary flow reserve (see Fig. 49-12). Over time, however, a view has emerged that CAD is a more complex process than can be simply defined dichotomously by a 50% or even a 70% luminal stenosis. Throughout the progression of plaque growth, there is a risk of transformation from a stable plaque to an unstable plaque, with the potential for an acute coronary syndrome (ACS) that abruptly alters the natural history of the disease process (see Chapters 41 and 51).³⁸ Plaque encroachment of the lumen occurs later in the process but has a potentially important impact on the patient's everyday quality of life by causing symptoms related to exertional ischemia.

Patient-Related Outcomes as a "Gold Standard"

The evolution of preventive therapies (see Chapter 42), such as 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (statins) to reduce cardiovascular risk has focused attention on the ability of global risk scores or noninvasive testing to assess risk of future events so that strategies to prevent future cardiac events can be instituted.³⁹ Thus, from the perspective of improving natural history, knowledge of whether a stenosis greater than 50% is present in a patient with stable anginal symptoms becomes less important than knowledge of the patient's risk for a cardiovascular event (i.e., cardiac death or nonfatal MI). After initial investigations of the performance of radionuclide imaging to detect or to rule out CAD (sensitivity and specificity), the trajectory of the literature has been toward gaining more understanding of how noninvasive imaging results assess prognosis and stratify the risk of future cardiac events.⁷ This trend has occurred in parallel with similar directions in primary prevention efforts, such as the use of a Framingham risk score, leading to lifestyle and treatment interventions to lower that risk.³⁹ In much the same way, risk stratification and assessment of prognosis by noninvasive imaging will inform clinical management decisions geared toward reducing risk of MI and cardiac death and optimizing the selection of patients for revascularization and medical therapies.

Risk Stratification in Stable Chest Pain Syndromes Definitions for Understanding the Literature

For prognostic assessment, an important goal is to detect patients at risk for "hard" cardiac events. This definition includes nonfatal MI as well as cardiac death or all-cause mortality, irreversible events important to prevent.⁴⁰ "Soft" cardiac events include revascularization and hospital admission for management of ACS or heart failure. Such events occur more often than the hard cardiac events and thus contribute to a larger number of endpoints for data analysis. These events, however, are not as important in terms of natural history and may be driven by subjective changes in symptoms and, in the case of revascularization, by the results of the imaging tests themselves.

Risk categories as described in the American College of Cardiology/American Heart Association (ACC/AHA) stable angina guidelines are (1) low risk, defined as a less than 1%/year risk of hard cardiac events; (2) intermediate risk, defined as a 1% to 3%/year risk; and (3) high risk, defined as a greater than 3%/year risk.⁴⁰ These definitions are conceptually linked to implied treatment strategies. Patients with greater than 3%/year risk would be most likely to benefit from a revascularization strategy, whereas those at low risk would be least likely to benefit from revascularization, in terms of natural history, and thus could be treated medically, with treatment directed against symptoms as well as risk factor modification.

FIGURE 16-30 Prognostic implications of MPI. **Middle panel**, Cardiac event rate (risk of cardiac death or MI) during long-term follow-up plotted as a function of the extent of inducible ischemia (the number of reversible perfusion defects). An exponential relationship exists between the extent of ischemia and the risk of a cardiac event. The brown line represents modeling of data points; magenta lines represent confidence limits. **A, B**, SPECT perfusion images in two patients with stable anginal symptoms. **A**, Small area of inferoapical ischemia (arrows). When this extent of ischemia is plotted on the graph (line to red circle at left within graph), the patient is placed in a low-risk category. **B**, By contrast, the large, markedly affected area representing severe anterior and septal ischemia in a second case places the patient in a high-risk group (line to red circle at right within graph). NS = not significant. (**A, B**, Modified from Ladenheim ML, Pollock BH, Rozanski A, et al: Extent and severity of myocardial hypoperfusion as predictors of prognosis in patients with suspected coronary artery disease. *J Am Coll Cardiol* 7:464, 1986.)

Relation Between the Extent of Perfusion Defect and Outcomes. Seminal studies in the 1980s demonstrated that the extent of perfusion abnormality by stress MPI has an important relationship with the subsequent likelihood of an adverse outcome (cardiac death or nonfatal MI). In patients presenting with chest pain and suspected CAD (without any previous known CAD-related history, such as MI or revascularization), the risk of cardiac death or MI increased as the number of reversible perfusion defects (i.e., the extent of inducible ischemia) increased (Fig. 16-30).

This concept has been confirmed many times by investigators around the world. Moreover, this robust concept not only applies to exercise stress MPI but also extends across the spectrum of procedural variables in nuclear cardiology, including different stressors (vasodilator pharmacologic stress, dobutamine stress), isotopes (²⁰¹Tl and ^{99m}Tc agents), and imaging protocols (including dual-isotope imaging).⁷ An example of data on risk stratification implying therapeutic management strategies is demonstrated by the images shown in Figure 16-30A and B: In two older men with typical exertional angina, it would be predicted that the probability of CAD is very high, according to established guidelines. What is not established from the clinical information, however, is the risk of cardiac events. This example demonstrates that patients presenting with similar symptoms might be identified as having specific natural histories on the basis of perfusion imaging data, with distinct implications for subsequent management.

Incremental Value of Perfusion Imaging. The term *incremental value* implies that MPI data provide information on natural history risk and outcomes that are additive to (incremental to) information from more available or less expensive tests, such as clinical data and stress ECG findings.

Stress MPI data have been shown to have incremental prognostic value when added to prognostic stress ECG instruments such as the Duke Treadmill Score, a well-validated instrument incorporating symptoms, treadmill performance, and stress ECG findings to predict natural history outcomes (see Chapter 13). In a group of 2200 patients with suspected CAD referred for nuclear testing, the Duke Treadmill Score was used to place patients in subgroups according to the risk of a hard event (Fig. 16-31). When information from stress MPI studies was incorporated, incremental value to predict outcome was demonstrated within each of the three Duke Treadmill Score risk categories.

The importance of this information in driving management decisions for patients can be illustrated by considering how clinicians would manage patients on the basis of certain amounts of information. With use of the Duke Treadmill Score information alone, the management of low-risk patients probably would be conservative,

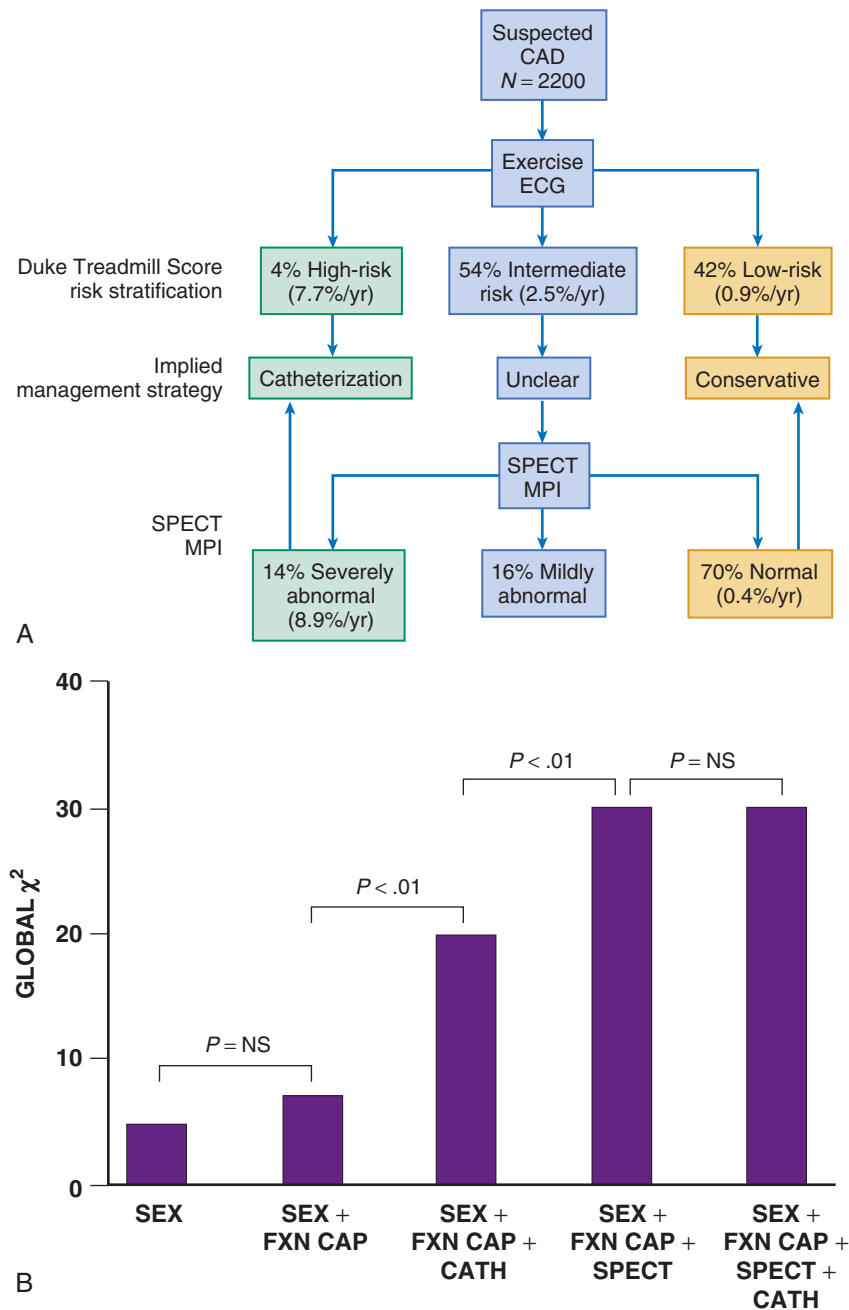

FIGURE 16-31 Incremental value of SPECT perfusion imaging. **A**, Comparison with the Duke Treadmill Score (DTS). A large group of patients with suspected CAD initially were risk-stratified using the well-validated DTS. Figures in parentheses are the observed annual event rates. A majority of the population is classified as intermediate risk by DTS, and management strategy is not clear. High-risk patients may be managed aggressively, and low-risk patients may be managed conservatively. Among patients originally determined to be in the intermediate-risk category by the DTS, almost 70% demonstrated normal findings on SPECT perfusion study, associated with a very low event rate. After SPECT MPI, more patients are classified at the “extremes” of risk (low or high), for which management is more clearly implied by the risk prediction. Thus the imaging data allowed further stratification and had incrementally better value compared with the DTS information. **B**, The incremental value of imaging data may be expressed as the incremental chi-square value, a statistical measure of the strength of the association of clinical, demographic, stress, or imaging factors to risk stratification. Among patients with known CAD who had undergone catheterization (cath), clinical information is added on the x axis, with the global chi-square value associated with the information depicted on the y axis. The larger the chi-square value, the stronger the relation between the combination of factors on the x axis and the natural history outcome of cardiac death or myocardial infarction. Even when anatomic information is available, the physiologic information provided by SPECT MPI adds significantly to risk prediction ability. FXN CAP = functional capacity. (A, Modified from Hachamovitch R, Berman DS, Kiat H, et al: Exercise myocardial perfusion SPECT in patients without known coronary artery disease: Incremental prognostic value and use in risk stratification. *Circulation* 93:905, 1996; B, modified from Iskandrian AS, Chae SC, Heo J, et al: Independent and incremental prognostic value of exercise single-photon emission computed tomography (SPECT) thallium imaging in coronary artery disease. *J Am Coll Cardiol* 22:665, 1993.)

and the management of high-risk patients would be likely to involve revascularization. The optimal management of intermediate-risk patients is unclear, but many probably would be referred for catheterization. In almost 70% of the patients in the intermediate Duke Treadmill Score category, however, stress perfusion study findings were normal (Fig. 16-31A), associated with a very-low-risk natural history, implying that conservative management would be a safe and effective strategy.

Another method used to demonstrate the incremental value of MPI data over that of clinical, stress, and even angiographic data involves the creation of a multivariable model to measure the strength of association of individual factors with the natural history outcomes.⁴¹ This often is illustrated by assessing the incremental chi-square value measuring the strength of the association of the factor with subsequent cardiac death and nonfatal MI (Fig. 16-31B).

Identification of Treatment Benefit After Risk Stratification. Although numerous studies intimate that the extent and severity of perfusion abnormality are related to subsequent natural history risk, few studies have documented reduction in that risk associated with a particular therapy. Current information suggests that more extensive ischemia determined by MPI identifies patients in whom revascularization may lead to an improvement in outcome. In a group of more than 10,000 patients with suspected CAD studied by stress MPI, the extent of ischemic myocardium predicted reduction in the risk of death with revascularization compared with medical therapy (Fig. 16-32), beginning at just over 10% of ischemic myocardium.⁴² As the percentage of ischemic myocardium increased, the magnitude of benefit of revascularization increased as well. Thus MPI data can predict the magnitude of a potential treatment benefit from revascularization, helping to guide management decisions.

Prognostic Value of Normal Myocardial Perfusion Imaging. A consistent finding in studies assessing prognosis has been the benign outcome associated with a normal stress MPI study. As summarized in the ASNC Imaging Guidelines,⁷ data on outcomes associated with normal findings on a stress SPECT MPI study involve almost 21,000 patients. In patients with a normal study result, the hard event rate (i.e., rate of cardiac death or nonfatal MI) occurring during an average follow-up period of 2 years is 0.7%/year. This concept applies across a broad spectrum of isotopes, protocols, and stressors.^{7,43} The prediction of low-risk outcome after a normal MPI study extends approximately 2 years after testing (i.e., the “warranty period”).⁴⁴ Patients who at baseline represent higher risk subsets (i.e., those with diabetes) are at slightly higher risk for an adverse outcome after normal results of a stress MPI study⁴⁵ consistent with Bayes’ theorem; that is, for a certain MPI finding, the posttest probability (outcome risk) is related in part to the pretest risk.

Even when angiographic CAD is present with a stable symptom complex, a normal stress MPI study result is associated with a low-risk outcome (approximately 0.9%/year).⁷ The mechanism for a normal MPI study result despite established CAD has not been conclusively demonstrated but may involve preserved endothelial function, allowing appropriate flow-mediated vasodilation during stress, reducing the impact of an angiographic stenosis on downstream myocardial perfusion. If this is true, such preserved endothelial function may identify a decreased susceptibility to plaque fissuring or rupture and a greater likelihood of a stable clinical course. Another mechanism may involve the presence of robust collaterals,

FIGURE 16-32 Predicting the magnitude of treatment benefit by revascularization. Risk of death is plotted as a function of the percentage of ischemic myocardium by SPECT perfusion imaging. The lines represent patients treated with medical therapy (Medical Rx) or revascularization. When the magnitude of ischemia exceeds approximately 12%, a potential survival benefit accrues to revascularization. (Modified from Hachamovitch R, Hayes SW, Friedman JD, et al: Comparison of the short-term survival benefit associated with revascularization compared with medical therapy in patients with no prior coronary artery disease undergoing stress myocardial perfusion single photon emission computed tomography. *Circulation* 107:2900, 2003.)

allowing normal stress perfusion in the setting of a stenosis, and protecting against infarction should the stenosis become completely occluded.

Dynamic Assessment of Prognosis by Serial Scintigraphic Studies

Although an important correlation exists between the extent of ischemia and subsequent outcome, the specificity of such determinations is low. That is, among patients with high-risk scintigraphic signs, only a minority suffer an important cardiac event during follow-up, and a majority of “high-risk” patients remain event-free. Because most of these high-risk patients undergo catheterization and intervention, many patients who will not have an event are receiving interventions to prevent these events in the minority. Clinicians accept this tradeoff, but evolving data suggest that the response of scintigraphic ischemia to medical therapy may allow more precise estimates of prognosis.

In the Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation (COURAGE) trial, patients with stable CAD who were randomly assigned to undergo percutaneous coronary intervention (PCI) in addition to receiving optimal medical therapy showed a greater reduction in scintigraphic ischemia compared with those patients randomly assigned to receive optimal medical therapy alone (see Chapter 54).⁴⁶ Whether patients receiving optimal medical therapy with residual ischemia on serial testing would benefit from more aggressive interventional therapy is a concept for future study. Until such data are available, the benefit of serial testing to assess for the presence of residual ischemia is uncertain.

Studies using either PET or SPECT assessment of perfusion have concordantly demonstrated improvement in stress perfusion after statin therapy (Fig. e16-8).⁴⁷ Because such therapy is unlikely to affect significantly the degree of luminal encroachment by a plaque lesion, these data suggest that improvement in perfusion may be a result of statin-mediated improvement in endothelial function. Favorable changes in perfusion may identify cohorts of patients gaining most benefit from statin therapy in terms of vascular stability, a concept that requires longer term follow-up assessment of such patients.

Detecting the Presence and Extent of Coronary Artery Disease

Noninvasive testing in patients with suspected CAD is commonly performed to determine the presence or absence of angiographic CAD. In this paradigm, angiography is the gold standard to define the presence or absence of CAD, and performance of the noninvasive

test is measured by its sensitivity (percentage of true-positive test results among those with CAD as defined by angiography) as well as by its specificity (percentage of true-negative test results among subjects without CAD).^{7,48} Published values of sensitivity to detect CAD and specificity to rule out CAD vary widely.⁷ An appreciation of the many factors that may potentially influence these performance characteristics is necessary for imaging data to be incorporated appropriately into clinical decision making. Such factors include either methodologic or physiologic factors.

Methodologic Influences on Sensitivity and Specificity

Referral Bias. The apparent accuracy of any noninvasive test to detect CAD depends on the indications for coronary angiography. Accuracy of a new diagnostic test usually is determined initially in patients who are undergoing coronary angiography. As the test becomes implemented in routine diagnostic strategies, its results determine which patients are to be referred for coronary angiography (Fig. 16-33). For example, patients with abnormal MPI findings are more likely to undergo coronary angiography than those with normal MPI findings. This inherent selection process results in a phenomenon termed *posttest referral bias*, in which the specificity of a diagnostic test declines over time as it is accepted into clinical practice and plays a gatekeeper role in determining which patients undergo angiography.⁷ In its extreme form, in which only patients with an abnormal test result are referred for angiography (as in Fig. 16-33), posttest referral bias drives the specificity to zero (all patients with normal coronary arteriograms have false-positive MPI results, and there are no true negatives). The same phenomenon artificially increases the sensitivity of the test and in its extreme drives the sensitivity to 100% (all patients with abnormalities on coronary arteriograms have true-positive findings on MPI, with no false negatives). This concept holds not only for MPI but also for any diagnostic test that might determine the indications for angiography.

The concept of “normalcy rate” has been developed in an attempt to compensate for this referral bias.⁷ Normalcy is calculated in the same manner as for specificity but includes only the imaging test results of patients with a clinically low or very low pretest likelihood of having CAD, whether or not they are referred for cardiac catheterization. Normalcy rates tend to be higher than specificity.

Angiography as the Gold Standard. In humans, coronary atherosclerosis is a complex disease most often involving the coronary arteries diffusely and not merely focally. Moreover, whether a given discrete stenotic lesion, imaged at rest during coronary angiography, results in a perfusion abnormality during stress is dependent on a number of factors besides the percentage degree of stenosis. These factors include the dilatory or constrictor response of the vessel during stress (mediated by endothelial function) and the presence or absence of collaterals.⁴⁸ For example, a vessel with 70% stenosis but with preserved endothelial function and a well-developed collateral supply may not be associated with an abnormality on stress MPI. In a diagnostic construct, such a result would be categorized as a false-negative finding, reducing MPI sensitivity. However, the MPI data may be providing the correct physiologic information about the functional significance of the angiographic finding, demonstrating that collateral flow during exercise or normal endothelial function or both are associated with preserved coronary blood flow reserve despite the coronary stenosis. This example illustrates the limitation of using angiography as a gold standard in evaluation of a physiologic modality.

Many published studies define CAD as 50% or greater stenosis, whereas others use a threshold of 70% or greater stenosis.^{6,7} Use of the former would decrease sensitivity (because some 50% to 70% stenoses are not hemodynamically significant) and increase specificity. By contrast, use of the latter threshold would increase sensitivity (because more such stenoses are likely to be associated with a perfusion abnormality), but decrease specificity, because any positive scan result with 50% to 70% stenosis would be considered false-positive.

Physiologic Influences on Sensitivity and Specificity. A number of disease processes involving the coronary vasculature or the myocardium may result in abnormalities in myocardial perfusion in the absence of a discrete coronary stenosis. In a diagnostic construct for CAD, such abnormalities would be labeled false-positive, reducing specificity (i.e., the test result is positive in the absence of epicardial CAD). However, MPI may actually be providing correct information about perfusion physiology.

Left Bundle Branch Block. Isolated reversible perfusion defects of the septum in patients with LBBB may be seen in the absence of

FIGURE e16-8 Improvement in perfusion after statin therapy. Three-dimensional surface-rendered models of myocardial perfusion before statin therapy (*left*) and after 6 weeks (*middle*) and 6 months (*right*) of therapy, viewed from the inferior surface of the heart. *White areas* represent normal perfusion, with *red, blue, and black* representing increasingly severe degrees of ischemia. Labels below each image show the extent of ischemia, expressed as a percentage of total myocardium. Substantial reduction in the degree of inferior wall ischemia occurs over the course of statin therapy. (Modified from Schwartz RG, Pearson TA, Kalaria VG, et al: Prospective serial evaluation of myocardial perfusion and lipids during the first six months of pravastatin therapy: Coronary artery disease regression single photon emission computed tomography monitoring trial. *J Am Coll Cardiol* 42:600, 2003.)

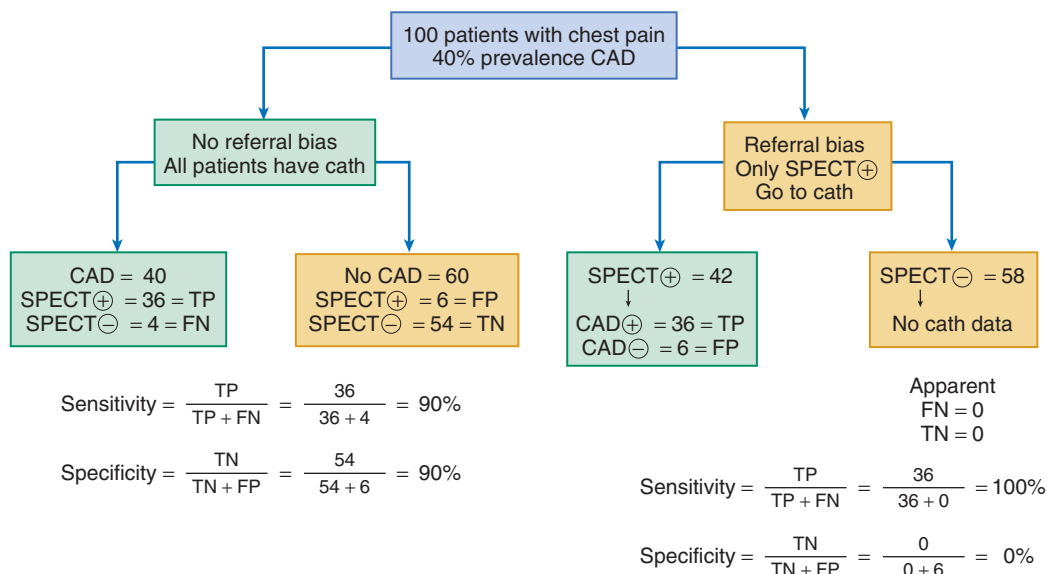

FIGURE 16-33 The effect of referral bias on specificity calculation. If the test being evaluated is used as the “gatekeeper” to coronary angiography, many patients in whom testing yields true negatives (i.e., those with a normal test result and no have CAD) will not undergo angiography, so their data will not be included in the specificity calculations (right). This has an effect of artificially reducing the apparent specificity of the noninvasive test in question. FN = false-negative; FP = false-positive; TN = true-negative; TP = true-positive. (Modified from Rozanski A, Diamond GA, Berman D, et al: The declining specificity of exercise radionuclide ventriculography. *N Engl J Med* 309:518, 1983.)

stenosis of the left anterior descending (LAD) coronary artery.^{2,7} This phenomenon may represent true heterogeneity of flow between the LAD and left circumflex arterial territories, related to delayed relaxation of the septum in LBBB leading to reduced coronary flow reserve in early diastole, or reduced oxygen demand as a result of late septal contraction, when wall stress is decreasing. Accordingly, the specificity and predictive value of a septal perfusion defect with LBBB are low. However, apical or anterior involvement in septal perfusion defects increases the specificity for CAD.⁷ Because a septal defect in LBBB most commonly is seen at high heart rates, pharmacologic stress improves specificity, and vasodilator stress is recommended in the setting of LBBB.⁷

Hypertrophic Cardiomyopathy. The asymmetric septal hypertrophy in many patients with HCM (see Chapter 66) can lead to the appearance of a greater amount of tracer uptake in the hypertrophied septum relative to the lateral wall, creating the impression of a mild lateral wall perfusion defect, especially when polar maps are employed.

Many reports have demonstrated myocardial perfusion abnormalities in patients with HCM in the absence of epicardial CAD.⁴⁹ Such findings have important pathophysiologic relevance: patients with fixed perfusion defects are likely to have thinned akinetic walls on echocardiography and diminished EF (Fig. 16-34). Of asymptomatic patients with HCM, approximately 50% have inducible, reversible perfusion abnormalities in the absence of CAD, typically involving the septum. Thus inducible perfusion defects in HCM that represent inducible myocardial ischemia, possibly related to microvascular abnormalities (see Chapter 66), have low specificity for CAD in patients with HCM. The blunted coronary flow reserve in patients with HCM is associated with a more unfavorable natural history.⁴⁹

Left Ventricular Hypertrophy. As with the experience in HCM, inducible perfusion abnormalities may develop in patients with pressure overload LV hypertrophy (LVH) related to either hypertension or aortic stenosis.⁷ In the absence of CAD, it is presumed that these abnormalities represent regional myocardial ischemia based on abnormal microcirculation and limited vasodilator reserve in patients with LVH. In general, however, studies in patients with LVH by ECG criteria have demonstrated an accuracy of MPI for detection of CAD that is comparable to that in patients without LVH. On the basis of such data, MPI is an ACC/AHA Guidelines class I indication for CAD detection when LVH is present on the ECG.⁷ SPECT imaging data in patients with LVH also have a risk stratification value similar to that in patients without LVH.⁵⁰

FIGURE 16-34 SPECT perfusion imaging in hypertrophic cardiomyopathy in young asymptomatic patients with normal coronary arteries. **A**, Fixed perfusion defect of the apex consistent with infarction, indicated by yellow arrowheads in the horizontal (HLA) and vertical (VLA) long-axis images, with a reversible defect of the anterior wall (yellow arrows in the VLA images). The hypertrophied septum is evident (white arrows in the HLA images). **B**, Extensive inducible silent ischemia in the anterior, lateral, and inferior walls (white arrows). Transient ischemic cavity dilation also is present, possibly related to subendocardial ischemia. (**A**, **B**, Based on data from O’Gara PT, Bonow RO, Maron BJ, et al: Myocardial perfusion abnormalities in patients with hypertrophic cardiomyopathy: Assessment with thallium-201 emission computed tomography. *Circulation* 76:1214, 1987; and Udelson JE, Bonow RO, O’Gara PT, et al: Verapamil prevents silent myocardial perfusion abnormalities during exercise in asymptomatic patients with hypertrophic cardiomyopathy. *Circulation* 79:1052, 1989.)

Dilated Cardiomyopathy. Abnormalities in myocardial perfusion are common in patients with dilated cardiomyopathy (DCM) despite normal epicardial coronary arteries.⁷ Several studies have demonstrated abnormal coronary flow reserve in these patients (see Chapter 65), and as with HCM, blunted flow reserve identifies a cohort of patients with DCM with a more unfavorable natural history.¹⁸ Such data support the relevance of the perfusion abnormalities rather than simply classifying them as false-positive if epicardial CAD is not present.

An important diagnostic consideration in patients with LV systolic dysfunction involves distinguishing those whose cardiomyopathy may be primarily due to CAD (many of whom have potentially reversible LV dysfunction) from those with idiopathic DCM. Although many patients with DCM may have perfusion abnormalities detected on MPI, the absence of perfusion abnormalities virtually excludes CAD as

FIGURE 16-35 SPECT perfusion images obtained during stress and at rest in a patient with heart failure. The images depict a dilated left ventricle but with normal perfusion patterns, suggesting a low likelihood that CAD is the cause of heart failure. HLA = horizontal long axis; SA = short axis; VLA = vertical long axis.

the cause of the cardiomyopathy⁵¹ (Fig. 16-35). Extensive perfusion abnormalities in the setting of LV dysfunction are virtually always associated with CAD rather than with DCM, especially when the perfusion defects are segmental.

Endothelial Dysfunction. Abnormalities in myocardial perfusion detected by SPECT MPI have been demonstrated in patients with coronary endothelial dysfunction, in the absence of “significant” epicardial vessel stenosis. That these perfusion findings represent true abnormalities in coronary flow reserve is supported by studies showing improvement in perfusion on follow-up MPI after treatment with medical therapies directed at improving endothelial function.⁵² Further support for this concept comes from CMR studies demonstrating blunted subendocardial coronary flow reserve in patients with angina and normal coronary arteries (see Chapter 17).⁵³

Sensitivity and Specificity of Myocardial Perfusion Imaging

ASNC imaging guidelines summarize sensitivity and specificity data from 33 studies involving 4480 patients undergoing exercise SPECT imaging.⁷ Sensitivity to detect CAD was 87% (range, 71% to 97%) in this pooled analysis, and specificity to rule out CAD was 73% (range, 36% to 100%). Few if any of these studies incorporated ECG-gated SPECT imaging of regional function or attenuation correction, techniques that appear to enhance specificity. For example, in one study of women undergoing coronary angiography, specificity was improved from 76% to 96% when gated SPECT ^{99m}Tc-sestamibi imaging was used compared with nongated SPECT ²⁰¹Tl.⁷

Influence of Perfusion Tracer on Detection of Coronary Artery Disease

Despite the expectation of improved diagnostic accuracy with use of ^{99m}Tc-based agents, on the basis of more favorable attributes as a radioisotope for gamma camera imaging compared with ²⁰¹Tl, studies comparing the widely used agents have not shown significant improvement in sensitivity or specificity. An exception is the demonstration of improved specificity in women with the use of ^{99m}Tc-sestamibi compared with ²⁰¹Tl, as noted earlier. Thus the choice of radiotracer for MPI does not notably affect the discrimination between the presence and absence of CAD. Published studies often include subjects who may not fully represent those in whom imaging poses the greatest challenges. It would be expected that the ^{99m}Tc-based agents, with their greater photon energy, would offer improved performance in obese patients and those with large breasts, as well as allowing the option of higher-quality gated images.

Influence of Automated Quantitation of Myocardial Perfusion Images on Detection of Coronary Artery Disease

Both intraobserver and interobserver variability in the visual analysis of myocardial perfusion images may be significant. Several

methods of quantitative analysis of MPI have been developed^{1,7} to reduce the variability in reading by “objectifying” image analysis, by comparing regional uptake values against a database of normal values.

Automated quantitative analysis systems are incorporated into most SPECT camera computer equipment. Some of the most common are Emory Toolbox, Cedars QPS, and 4D-MSPECT¹ (Fig. 16-36). Although published data do not clearly demonstrate improved sensitivity or specificity of these programs over visual analysis for CAD detection, such data arise from expert centers, often where the quantitative software was developed, and the visual analysis data are derived from experienced readers in laboratories with excellent quality control.

In practice, the use of contemporary quantitative programs can improve image acquisition quality as well as interpretation. Some programs incorporate motion-sensing algorithms that interrogate the raw data and alert the technologist that motion correction may be needed.

Pharmacologic Stress Testing for Detecting Coronary Artery Disease

Reports examining the sensitivity and specificity of vasodilator pharmacologic stress combined with MPI for the detection of CAD have achieved results similar to those reported with exercise stress. A pooled analysis involving 2465 catheterized patients in 17 studies⁷ demonstrated sensitivity of 89% and specificity of 75%, similar to values from exercise SPECT MPI studies.

The more powerful hyperemic stress response achieved with vasodilator stress compared with exercise might be expected to result in improved sensitivity to detect CAD, particularly more moderate stenoses. Such improvement has not been demonstrated, possibly because of the “roll-off” property of the common perfusion tracers, caused by diffusion limitation at hyperemic blood flow levels (see Fig. 16-22).⁶ Thus the more favorable hyperemic stress achieved with pharmacologic stress is offset by the lack of linear tracer uptake in the areas with the highest flow.

The diagnostic ability of dobutamine stress imaging appears to be generally similar to that of other pharmacologic and exercise stress modalities for the detection of CAD.⁷ However, because maximal coronary flow reserve is not achieved as often as with vasodilator pharmacologic stress and side effects are substantial, dobutamine is recommended only when adenosine, dipyridamole, or regadenoson is contraindicated, such as in a patient with important reactive airways disease.

Effect of Submaximal Exercise Performance on Coronary Artery Disease Detection

The sensitivity of MPI to detect CAD is optimized by achieving the highest possible level of oxygen demand to stimulate the greatest increment in coronary flow reserve. In exercise ECG testing, sensitivity to detect CAD falls significantly if greater than 85% of maximum predicted heart rate for age is not achieved (see Chapter 13).⁴⁰ Because perfusion heterogeneity usually develops at a lower degree of supply-demand mismatch than ECG changes, the sensitivity of MPI to detect CAD is maintained at somewhat lower workloads.⁷ However, the extent and severity of reversible perfusion defects may be diminished at submaximal compared with maximal workloads, which may affect the prognostic value of the test.

Thus the selection of a stress protocol can be summarized as follows^{2,7}: Exercise is the preferred stressor, because it allows the optimal potential association of symptoms with perfusion abnormalities. The use of exercise also allows incorporation of validated stress test criteria such as the Duke Treadmill Score, heart rate reserve, or heart rate recovery with the MPI data.²⁴ For patients who cannot exercise adequately, vasodilator stress with adenosine, dipyridamole, or regadenoson is the procedure of choice; dobutamine is used for patients with a contraindication to the vasodilators.²⁵ For patients who begin exercise but do not reach 85% of maximum predicted heart rate for age or who do not reach an appropriate symptomatic

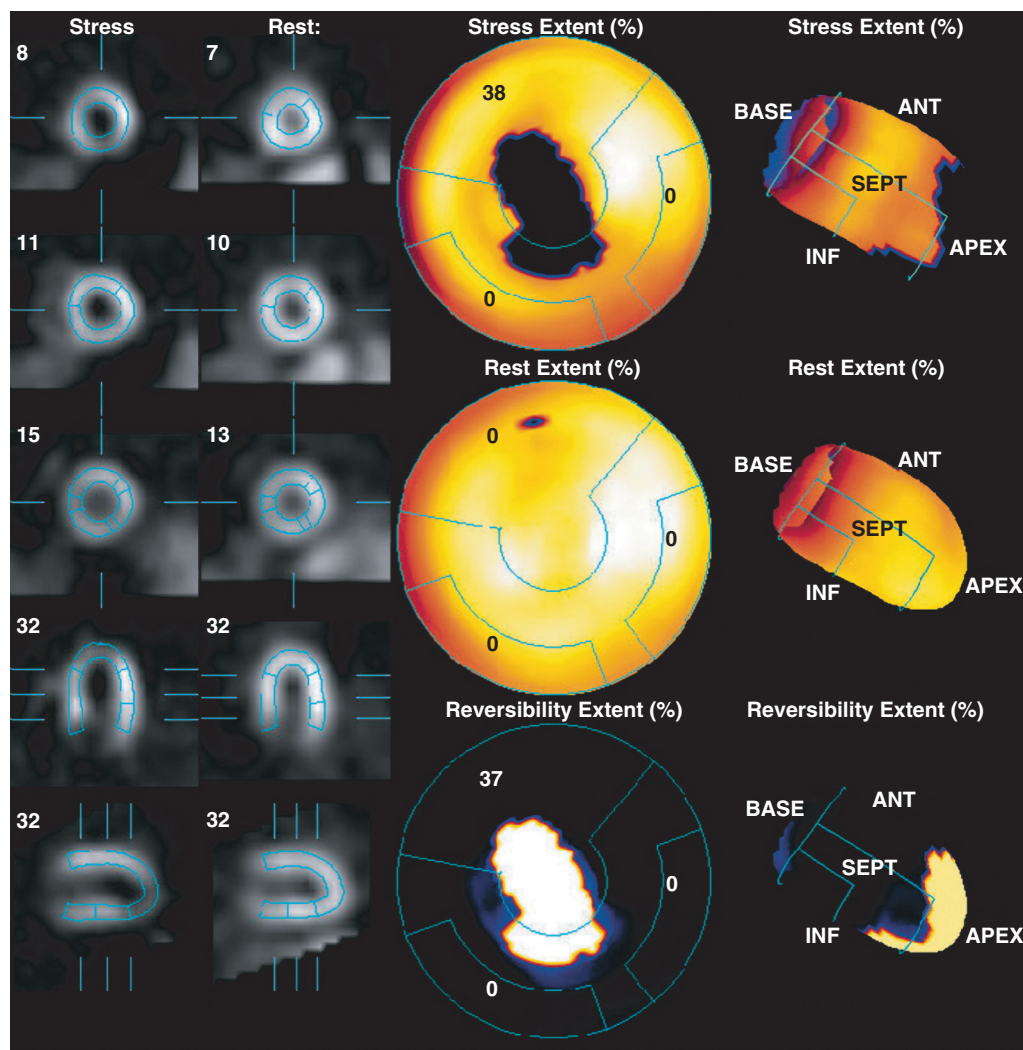

FIGURE 16-36 Automated quantitative analysis software display. Selected short- and long-axis tomograms from stress and rest studies (two left columns) are automatically segmented and scored. Bull's-eye plots are created (third column) representing the stress (top) and rest (middle) data and demonstrate a large apical reversible defect. The bottom bull's-eye plot displays the extent of ischemic myocardium (white area), which measures 23% of the total myocardium. The bull's-eye information also is displayed in a three-dimensional format (right column, top, middle, and bottom). Numbers on the bull's-eye maps represent the percentage of the vascular territory that is abnormal. ANT = anterior; INF = inferior; SEPT = septal. (Images courtesy Guido Germano, PhD.)

endpoint, isotope injection can be withheld, the exercise portion of the test terminated, and vasodilator stress performed to optimize diagnostic and risk stratification information.

Defining the Extent of Coronary Artery Disease. In formulating a management strategy for patients, it is important to determine the extent of disease rather than just the presence or absence of disease. The term *extensive CAD* refers to angiographic patterns of CAD that have prognostic significance and suggest treatment benefit from revascularization, such as left main or severe three-vessel CAD involving the proximal LAD coronary artery.

Detecting Multivessel Coronary Artery Disease. SPECT MPI is limited by the *relative* nature of the perfusion information: If all areas are hypoperfused in the presence of three-vessel CAD, the least hypoperfused area appears normal and the true extent of CAD may be underestimated. However, incorporation of other findings, including regional functional abnormalities, can be used to estimate more correctly the probability of disease extent.

Wall motion abnormalities on post-stress gated SPECT images may be of benefit in the detection of extensive CAD. In one study,⁵⁴ incorporating the finding of poststress wall motion abnormality on gated SPECT imaging with the degree of perfusion abnormality allowed improved sensitivity (85% to 91%) for detection of proximal 90% LAD stenoses or multivessel disease related to 90% or greater proximal stenoses. Similar findings have been reported to improve detection of

three-vessel CAD.⁵⁵ Numerous reports suggest that nonperfusion signs such as lung uptake of ²⁰¹Tl after stress, or transient ischemic dilation, raise the probability of multivessel CAD for any given extent of perfusion abnormality.^{2,7}

Another approach that has undergone increasing validation is measurement of myocardial flow reserve (MFR) (the ratio of stress to rest myocardial blood flow) using PET imaging technology. This can be done using available perfusion tracers such as ⁸²Rb. In a study of 120 patients undergoing stress ⁸²Rb perfusion imaging and coronary angiography, the MFR data were more powerful than the stress perfusion pattern at discriminating the presence from the absence of three-vessel CAD, and this measure was an independent predictor of the presence of three-vessel CAD.⁵⁶

Findings unrelated to imaging also are useful in enhancing the diagnosis of left main or three-vessel CAD. The development of greater than 2 mm of ST depression or hypotension on ECG treadmill testing increases the likelihood of left main or three-vessel CAD.²⁴

Detection of Coronary Artery Disease in Women. The detection of CAD by exercise ECG testing is problematic in women (see Chapter 77).⁴⁰ The use of ²⁰¹Tl for detecting CAD in women is limited by potential artifacts associated with breast attenuation, resulting in false positives and reduced specificity. The use of ^{99m}Tc-labeled tracers should improve specificity because these agents are associated with slightly less tissue attenuation, as demonstrated in a study comparing ²⁰¹Tl SPECT with ^{99m}Tc-sestamibi-gated SPECT for the detection of angiographic CAD.⁶ With the incorporation of gated SPECT sestamibi

imaging, a specificity of 92% was achieved in one study, compared with 67% with ^{201}Tl (see Fig. 16-12).

Detection of Coronary Artery Disease in Valvular Heart Disease. Several studies have evaluated the use of MPI in the assessment of concomitant CAD in patients with valvular heart disease; most of the published studies involved patients with aortic stenosis. Sensitivity of MPI has ranged from 61% to 100%, with specificity of 64% to 77%.⁷ Although it is potentially useful in selected cases to assist in symptom evaluation, these performance characteristics are not sufficient to preclude the use of coronary angiography to define the presence of CAD in patients being considered for surgery (see Chapter 63).³⁵

Radionuclide Ventriculography for Detection of Coronary Artery Disease. Early reports of exercise RVG to detect CAD included predominantly patients with extensive CAD, resulting in high sensitivity. Because the test was more widely applied to populations with less extensive disease, sensitivity values were lower. However, although the EF response to exercise may be a relatively insensitive marker of CAD, it is a powerful prognostic marker.⁷

Because the LVEF response to exercise may be normal in many patients with less extensive CAD, a regional wall motion abnormality during exercise may be more sensitive for identification of CAD. RVG data during exercise usually are acquired in only one view, the left anterior oblique “best septal” view.¹⁴ Visualization of the inferior wall is therefore limited, and regional wall motion abnormalities are insensitive markers of disease of the right coronary artery.

The normal range for an exercise EF response initially was defined by values for a group of young normal volunteers, a population that differs from those with chest pain and normal coronary arteriograms. Posttest referral bias has been invoked to explain the decline in specificity for exercise RVG. As with a normal MPI study, however, a preserved ventricular response to exercise is associated with a good prognosis,¹⁴ despite the presence of CAD. In contrast with studies of MPI demonstrating little change in the ability to detect CAD at slightly submaximal workloads, the sensitivity for detection of CAD by exercise RVG is impaired at submaximal workloads.¹⁴

Although exercise RVG is rarely used in contemporary practice, the EF response to exercise or the absolute value of the exercise EF is a powerful prognostic indicator in suspected or known CAD, and these data have informed the contemporary use of poststress ECG-gated SPECT imaging as well as stress echocardiography (see Chapter 14).

Patients with Established Coronary Artery Disease

Several potential roles for SPECT MPI in patients with established CAD are recognized. Clinical questions may remain after angiography regarding the “physiologic significance” of stenotic lesions. The results of stress-rest SPECT MPI correlate generally with invasive measures of coronary flow reserve. Moreover, improvement of ischemia on SPECT imaging is a common finding after successful PCI, suggesting that SPECT MPI can identify the “culprit” ischemic lesion.⁷

Imaging after Coronary Artery Bypass Surgery

In patients in whom recurrent symptoms develop after coronary artery bypass graft surgery, SPECT MPI can accurately detect the presence and location of graft stenoses, even if the symptoms are atypical for ischemia.

A number of studies have concordantly demonstrated the value of SPECT MPI in risk stratification of patients after coronary artery bypass grafting (CABG), especially late after CABG, even in the absence of symptoms.⁷ The extent of perfusion abnormality is related to the subsequent risk of cardiac death and nonfatal MI, and SPECT information has incremental predictive value over clinical and stress data. Because the risk of cardiac events generally is low in the early years after CABG, routine stress MPI for detection of ischemia in an asymptomatic patient is considered an “uncertain” indication for testing by Appropriate Use Criteria.⁵⁷ Nonetheless, in a study of almost 900 asymptomatic patients studied with SPECT MPI after CABG,⁵⁸ perfusion defects were common and were associated with significantly increased relative risk of death or major events (as was impaired exercise capacity), even when controlling for time after CABG. In symptomatic post-CABG patients, such information can

guide the need for catheterization and intervention. In asymptomatic patients, in whom aggressive secondary prevention strategies should be in place, the implications for clinical decision making are less clear. In such cases, the extent of SPECT abnormality is important, because a more extensive perfusion abnormality is associated with a progressively higher risk of subsequent cardiac death or MI⁵⁸ and at some threshold may justify an invasive approach.

Imaging after Percutaneous Coronary Intervention

Exercise MPI is superior for detecting the presence and location of restenosis after PCI compared with exercise ECG, and current guidelines consider stress imaging in symptomatic patients after PCI as appropriate.⁵⁷ The extent of SPECT MPI abnormality in patients studied after PCI is associated with the subsequent risk of cardiac death or MI on long-term follow-up, even late after PCI, and this appears to hold true in patients even in the absence of symptoms.⁵⁹ Thus, although routine assessment of asymptomatic patients after PCI with SPECT MPI is considered inappropriate (within 2 years) or uncertain (after 2 years),⁵⁷ important information may be gleaned by imaging in symptomatic patients to guide decisions for reintervention and in selected high-risk asymptomatic patients late after PCI to assess subsequent risk.

Very early after PCI, SPECT MPI may demonstrate a mild reversible defect in the territory of the treated vessel (although less severe than before PCI).⁷ This defect may be due to delayed return of full coronary flow reserve after PCI, representing a true physiologic phenomenon.

Left Ventricular Function During Exercise in Patients with Coronary Artery Disease

The EF response to exercise (as determined by exercise RVG) is a reflection of the impact of regional ischemia on global LV performance. Even among patients with three-vessel CAD by angiography, the EF response to exercise may be maintained. This finding may reflect the possibility that only small areas of the left ventricle become ischemic if some of the stenotic lesions are not physiologically significant or if distal vessels are well collateralized. Patients with three-vessel disease who exhibit an abnormal exercise EF response are at high risk for adverse events during follow-up and consequently are more likely to benefit from revascularization.⁷ By contrast, patients who manifest a more normal EF response to exercise have a more favorable natural history and are therefore less likely to benefit from revascularization.¹⁴

Detection of Preclinical Coronary Artery Disease and Risk Stratification in Asymptomatic Subjects

Because sudden cardiac death is too often the first manifestation of CAD, interest in screening populations for CAD or for CAD risk is considerable. On the basis of Bayesian principles, the low prevalence of CAD in the general asymptomatic population results in low predictive value for a positive test result, although negative predictive value is high. Current guidelines and appropriate use criteria do not recommend routine stress MPI in asymptomatic populations.^{7,57}

In some circumstances, however, the baseline risk of a specific asymptomatic population may warrant testing with MPI. In a study of asymptomatic siblings of patients with known CAD, abnormal SPECT MPI was associated with a fivefold increase in risk for cardiac events, with higher relative risk if results on both stress MPI and ECG were abnormal.⁶⁰ A key question in considering testing such as SPECT MPI in asymptomatic populations is how the information will be used to manage or to reduce risk. Current guidelines suggest aggressive risk factor reduction therapy in those at high clinical risk for the development of vascular disease.³⁹ Whether further intensification of risk factor reduction in the setting of an abnormal imaging test, or diminished aggressiveness of risk factor reduction in the setting of a normal MPI study, results in improved outcomes is unproven and worthy of study.

Patients with diabetes are at significant risk for CAD development and cardiac events. An emerging body of literature suggests that a

substantial proportion of asymptomatic diabetic patients have abnormal SPECT MPI studies and that such patients may be at even higher risk for events over time. Studies suggest that results of SPECT MPI studies are abnormal in 20% to 40% of asymptomatic diabetic patients, often with evidence of inducible, silent ischemia.⁶¹ SPECT MPI demonstrates substantial risk value in stratification in patients with diabetes, with risk being higher for any given perfusion abnormality than in nondiabetic patients. However, a randomized trial of screening asymptomatic diabetic patients with stress SPECT MPI showed no differences in outcomes during long-term follow-up between those who were screened and those not screened, with event rates low in both groups.⁶¹ Thus appropriate use criteria at present do not suggest the need for routine screening in asymptomatic diabetic patients with stress SPECT MPI.⁵⁷

Myocardial Perfusion Imaging after CT Coronary Calcium Imaging or CT Angiography. With the growing availability and use of noninvasive CT cardiac imaging (see Chapter 18), clinicians are now commonly faced with patients with substantial coronary artery calcium (CAC), raising the possibility of multivessel CAD (see Fig. 18-12), or with apparent moderate or even severe stenoses seen on CT coronary angiography, raising questions about physiologic significance and risk stratification.

SPECT MPI and Coronary Calcium Imaging. Although extensive CAC and a high CAC score are indicative of atherosclerosis, studies to date have suggested that even extensive CAC is associated with important myocardial perfusion abnormalities in only a minority of patients. In one study of more than 1000 patients (approximately 50% of whom were asymptomatic),⁶² only approximately 10% of those with the highest CAC scores (Agatston score of >400) had abnormal perfusion on stress SPECT MPI, and only 5% had “high-risk” SPECT MPI perfusion patterns warranting consideration of potential benefit of revascularization (Fig. e16-9A). Thus, although the extensive CAC on CT imaging is well validated to represent subclinical atherosclerosis deserving of aggressive risk factor modification, it does not always indicate obstructive stenoses resulting in reduction in coronary flow reserve. On the basis of this concept, stress SPECT MPI is considered to be an appropriate test to determine the need for and potential benefit of catheterization and potential revascularization after CT imaging demonstration of CAC, when baseline coronary heart disease risk is high and the Agatston score is greater than 100.⁵⁷ With lower baseline risk and lower Agatston scores, SPECT MPI is considered inappropriate or of uncertain usefulness.⁵⁷

Refining Risk Stratification by Incorporating Both CT Calcium Imaging and SPECT MPI. Substantial literature now documents that patients with CAC, especially if extensive, are at higher risk for cardiac events over time compared with those with no CAC. Yet many with extensive CAC exhibit normal stress perfusion on MPI, a finding that extensive published data suggest is associated with low risk. How can these seemingly contradictory bodies of literature be reconciled? It is important to understand that “high risk” is a relative term—that is, patients with extensive CAC are at higher risk than those without CAC, but among those with extensive CAC, most will still not experience cardiac events. For example, in the Multi-Ethnic Study of Atherosclerosis (MESA), there was a clear gradient of risk as CAC scores increased, but the absolute risk of events was low (roughly 1%/year even among persons with high calcium scores) (see Fig. 18-12).⁶³ Hence combining data from CAC and SPECT MPI may provide a refinement of risk stratification.⁶⁴ Conceptually, those patients with no CAC and normal SPECT MPI findings should have the lowest risk, and those patients with both evidence of CAC and abnormal findings on SPECT MPI the highest risk. Patients with either CAC or SPECT MPI abnormalities should have an intermediate risk. Thus information from the two testing modalities may be complementary in refining the risk assessment of future coronary events, thereby curtailing the aggressiveness of primary prevention. Studies are ongoing in this regard.

SPECT MPI and CT Angiography. With the growing availability and technical evolution of multidetector CT angiography (see Chapter 18), clinicians are increasingly faced with questions about the physiologic significance of noninvasively detected coronary stenoses. Whereas current CT angiography data demonstrate high sensitivity and moderate specificity to detect or rule out obstructive stenoses, the spatial resolution is still insufficient for accurate determination of the severity of an individual stenotic lesion consistently and reliably, particularly when the severity of stenosis is in the intermediate range.

Moreover, stenoses are particularly difficult to detect, to rule out, or to quantitate when a coronary segment is heavily calcified. SPECT MPI can assess the physiologic significance of a stenosis and, in symptomatic patients, link the perfusion abnormality to the patient’s symptoms and identify the culprit coronary stenosis. In one study representative of the literature to date,⁶⁵ many stenoses considered obstructive (i.e., >50% stenosis) by CT angiography were associated with normal findings on stress SPECT MPI (Fig. e16-9B). These important data give pause to the concept of moving directly to invasive angiography (and potential PCI) after CT angiography and suggest that assessment of the physiologic significance of coronary stenoses identified by CT angiography may be important for clinical decision making.

Acute Coronary Syndromes

Application of Radionuclide Imaging: Answering the Clinical Questions

For patients with suspected ACS, radionuclide imaging techniques can both play a diagnostic role (is the clinical presentation due to ischemia and CAD?) and provide prognostic information. Among patients who present with an ACS and ST-segment depression or elevation (see Chapters 52 and 53), the typical role of imaging is in the stabilized patient after angiography and PCI to provide risk stratification information to drive management strategies aimed at improving natural history.

Suspected Acute Coronary Syndromes in the Emergency Department

Many patients presenting to EDs with symptoms suggestive of ACS but with nondiagnostic findings on initial ECG and biomarker assays are admitted to an observation unit for serial biomarker studies and possible stress testing.^{99m}Tc-based perfusion agents may be administered to a patient in the ED at rest, with images acquired 45 to 60 minutes later,⁶⁶ and because redistribution is minimal, images reflect myocardial blood flow at the time of injection.

In this setting, negative predictive value for ruling out MI is high in all observational series.⁶⁶ Patients with positive MPI have a higher risk of cardiac events during the index hospitalization as well as during follow-up (Fig. 16-37). Thus rest SPECT MPI can provide information to assist triage decisions for or against hospital admission from the ED.

The Emergency Room Assessment of Sestamibi for Evaluation of Chest Pain (ERASE Chest Pain) trial⁶⁷ in 2475 patients with symptoms suggestive of ACS randomly assigned subjects to receive an MPI strategy or to usual ED care and reported a significant 20% relative reduction in unnecessary hospital admissions of patients ultimately found not to have ACS among those assigned to MPI. The imaging data were among the most powerful factors associated with the decision to discharge the patient appropriately from the ED.

Thus evidence from controlled, randomized trials suggests that incorporation of SPECT MPI in ED evaluation of patients with suspected ACS but no definitive ECG changes can improve triage decisions. Rest MPI in this setting is considered to be an appropriate test for this indication.⁵⁷

Non-ST-Segment Elevation Myocardial Infarction and Unstable Angina

Guidelines recommend that patients with high-risk clinical characteristics in the setting of unstable angina undergo direct catheterization (see Chapter 53).³⁸ Contemporary clinical trials suggest that patients with positive biomarker assays, or those with a high-risk Thrombolysis in Myocardial Infarction (TIMI) score, benefit in terms of outcomes from an “invasive” strategy.³⁸ For patients with intermediate or low clinical risk (i.e., with “medically stabilized” unstable angina), stress MPI has been shown to have substantial risk stratification value and is considered an appropriate test.⁵⁷ Patients without ischemia or infarction, especially in the presence of preserved LV function, have a low-risk outcome, suggesting that such patients can be managed conservatively without catheterization, whereas patients with significant inducible ischemia are at high risk and thus are selected for intervention (Fig. 16-38).

FIGURE e16-9 A, In a study of 1195 patients without known CAD who underwent both SPECT perfusion imaging and assessment of coronary calcium by computed tomography (CT), the x axis categorizes patients by the age-corrected percentile of coronary calcium. Even when coronary calcium at a level greater than 90% for age is present, only 11% of patients had ischemia involving more than 5% of the left ventricle on SPECT, and only approximately 5% of such patients had ischemia involving more than 10% of the left ventricle. **B**, Prevalence of an abnormal SPECT perfusion study based on results of multislice CT (MSCT) angiography. Even when “obstructive” CAD (stenosis >50%) is confirmed by CT angiography, abnormal perfusion is present in only approximately 50% of patients. (**A**, Modified from Berman DS, Wong ND, Gransar H, et al: Relationship between stress-induced myocardial ischemia and atherosclerosis measured by coronary calcium tomography. *J Am Coll Cardiol* 44:923, 2004; **B**, modified from Schuijff JD, Wijns W, Jukema JW, et al: Relationship between noninvasive coronary angiography with multi-slice computed tomography and myocardial perfusion imaging. *J Am Coll Cardiol* 48:2508, 2006.)

FIGURE 16-37 Example of rest SPECT images in a patient evaluated in the ED with chest pain and nondiagnostic initial electrocardiographic findings. A severe inferolateral resting perfusion defect (arrow, all images) suggests ischemia at rest or infarction in that territory. Subsequent emergent angiography demonstrated an occluded left circumflex artery. HLA = horizontal long axis; SA = short axis; VLA = vertical long axis.

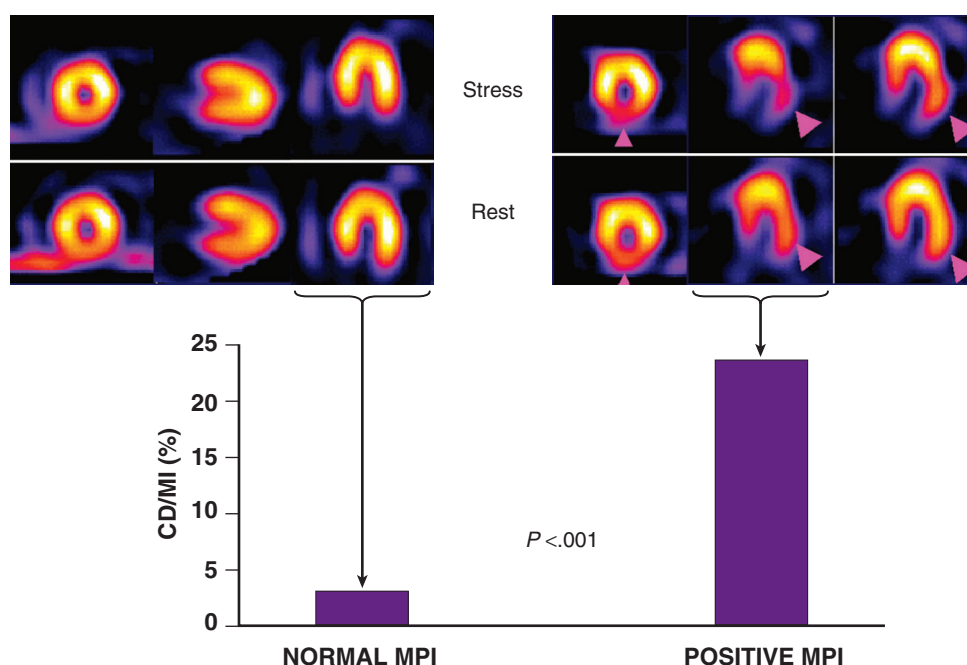

FIGURE 16-38 SPECT perfusion imaging in patients after medical stabilization of unstable angina. **Upper left**, Normal study findings, associated with a low risk of cardiac events during follow-up, suggesting that such a patient can be managed conservatively without catheterization but with aggressive secondary preventive strategies. The **bottom graph** is a summary of predictive values of SPECT imaging in the aftermath of unstable angina from multiple studies. Similar to the concepts in populations with stable chest pain, abnormal perfusion imaging after unstable angina is associated with a substantial increase in the risk of cardiac death or MI (CD/MI) during follow-up. **Upper right**, An example of a high-risk stress-rest SPECT MPI study result in the aftermath of unstable angina. Despite the stabilization of symptoms, extensive reversible perfusion abnormalities in the inferior and lateral walls suggest high risk of cardiac death or myocardial infarction, or both, during follow-up. This patient would therefore be managed more aggressively with catheterization and intervention. (Modified in part from Brown KA: *Management of unstable angina: The role on noninvasive risk stratification*. *J Nucl Cardiol* 4:S164, 1997.)

Although the results of randomized clinical trials, such as Treat Angina with Aggrastat and Determine Cost of Therapy with an Invasive or Conservative Strategy (TACTICS)–TIMI 18 and others, suggest slight superiority of an invasive approach in patients with unstable angina or non–ST-segment elevation MI (NSTEMI), subgroup analyses indicate that an important proportion of patients may be well managed by the conservative strategy of risk stratification by MPI followed by more selective catheterization and intervention. Moreover, a large randomized trial of patients with ACS and positive troponin T reported no difference in outcomes between an invasive strategy and a more selective invasive strategy in which patients were examined for ischemia before proceeding with catheterization while receiving contemporary aggressive medical therapy.⁶⁸ Therefore patients without elevation of troponin or high TIMI risk score may be potentially managed by a more conservative approach with risk stratification by use of imaging techniques.^{38,57}

ST-Segment Elevation Myocardial Infarction

Clinical variables such as recurrent ischemia, heart failure, and nonacute arrhythmias during hospitalization for acute ST-segment elevation MI (STEMI) identify a subgroup of patients at high risk in whom early catheterization and intervention are indicated (see Chapter 52).⁶⁹ Patients surviving the initial acute period, however, may have a relatively stable course, and current guidelines suggest that noninvasive risk stratification before hospital discharge is appropriate.^{7,69}

Assessment of Inducible Ischemia after Acute Myocardial Infarction

Three major determinants of risk after an acute MI are the residual LV function at rest, the extent of ischemic, jeopardized myocardium, and the susceptibility to ventricular arrhythmias. Gated SPECT MPI can provide much of this information comprehensively and thus has the potential to be the single most important test in the stable patient after STEMI.

In early studies examining the relation of MPI to outcomes in stable patients after MI, ²⁰¹Tl scintigraphic data contained the most robust information on stratifying post-MI risk. A “low-risk” ²⁰¹Tl image (no reversible defects and no lung uptake) was associated with a low-risk outcome after MI.⁴¹

An important proportion of patients who have sustained an uncomplicated MI are not able to exercise, even to a submaximal workload. With use of pharmacologic stress MPI in the post-MI setting, the presence of reversible defects has been reported as the only significant predictor of cardiac events on multivariable analysis,⁴¹ whereas the absence of reversible defects identified a low-risk cohort.

Studies in the reperfusion era have reported generally similar results regarding the relation of stress-induced ischemia to post-MI outcomes. In a study of 134 consecutive patients tested within 14 days of an uncomplicated MI, the extent of ischemia on SPECT MPI was the only significant variable associated with a future cardiac event on Cox regression analysis (Fig. e16-10). The extent of SPECT

ischemia remained strongly correlated with cardiac events in those who received thrombolytic therapy. The quantitated extent of ischemia on adenosine SPECT MPI also has been shown to be an important predictor of cardiac events in post-MI risk stratification. Post-MI patients with extensive inducible ischemia are at high risk for future cardiac events, and interventional management is likely to result in improved outcome.

Very Early Post-Myocardial Infarction Risk Stratification

Because pharmacologic vasodilator stressors induce coronary hyperemia with only minimal increments in oxygen demand, pharmacologic stress MPI may potentially be performed safely even very early after MI. This concept was examined in a study of 451 patients randomly assigned to a standard post-MI evaluation strategy or to a strategy incorporating dipyridamole SPECT MPI 2 to 3 days after uncomplicated MI. The testing was safe, and MPI supplied better risk

FIGURE e16-10 A, Risk of cardiac event during long-term follow-up after MI is predicted by the combination of infarct size (represented by LVEF) and the extent of reversible ischemia. As the extent of inducible ischemia increases (x axis) and the LVEF decreases (y axis), the outcome risk increases. The *blue lines* represent isobars of 10%, 25%, 50%, and 75% risk of an adverse event during post-MI follow-up. (The *large red circle* refers to the images in **B**.) **B**, SPECT images obtained in a patient studied several days after acute ST-segment elevation MI and medical stabilization. Besides the fixed defect representing the infarct in the anterior wall and apex (*arrowheads*), extensive inducible ischemia is evident both within and remote from the infarct territory (septum and inferior walls, *arrows*), involving 25% of the ventricle. Gated SPECT EF was 38%. On the basis of the data in **A**, there is an approximately 25% risk of a post-MI adverse event (*large red circle* in **A**). HLA = horizontal long axis; SA = short axis; VLA = vertical long axis. (Modified from Mahmarian JJ, Mahmarian AC, Marks GF, et al: Role of adenosine thallium-201 tomography for defining long term risk in patients after acute myocardial infarction. *J Am Coll Cardiol* 25:1333, 1995.)

stratification data predicting outcomes than the submaximal stress MPI data.²⁵ Thus pharmacologic stress can safely allow management decisions to be made earlier in the post-MI course.

Studies Examining Both Perfusion Imaging and Left Ventricular Function after Acute Myocardial Infarction

LVEF after MI is inversely related to subsequent short and long-term mortality. The availability of gated SPECT imaging to evaluate myocardial perfusion and LV function simultaneously raises an important question about the incremental information provided by combining the analysis of perfusion and function information within one test.

One study comprehensively evaluated LV function and adenosine SPECT MPI in patients in relation to long-term cardiac events (see Fig. e16-10). Both the extent of perfusion defect and LVEF provided superior risk categorization to that achievable with either variable alone. These findings strongly suggest that perfusion abnormalities and LVEF after MI have complementary roles, and their measurement together powerfully categorizes patients' risk in the post-MI setting.

Radionuclide Imaging in Acute Coronary Syndromes: Research Directions

Imaging of Ischemic Memory. A possible future approach to risk stratification in patients with suspected ACS involves the imaging of fatty acid metabolism. As noted earlier, after a regional ischemic insult, abnormalities in fatty acid metabolism may persist long after perfusion has returned to normal, a finding termed ischemic memory. Imaging of fatty acid metabolism may therefore allow assessment of recent ischemia. Uptake of the radiolabeled fatty acid analogue BMIPP has been imaged with SPECT 1 to 5 days after presentation in patients with suspected ACS. In an early study, BMIPP imaging showed greater sensitivity than did rest MPI in identifying the presence and site of the culprit coronary stenosis⁷⁰ (Fig. 16-39). Recent multicenter data have shown that SPECT imaging of fatty acid metabolism in patients presenting to EDs with suspected ACS adds incremental value to initial clinical information for assessment of the presence or absence of an ACS.⁷¹ Future studies will determine whether such techniques can help guide management decisions.

Imaging in Heart Failure

Is Coronary Artery Disease the Cause of Heart Failure?

Determination of whether LV dysfunction represents the consequences of CAD or is caused by one of the many other disorders of nonischemic etiology disorders is a critical early step in the management of patients with heart failure. Because CAD is the most common cause of heart failure in developed countries,⁷² noninvasive assessment of myocardial ischemia and viability would identify the subgroup of patients with heart failure who have a potentially reversible degree of LV dysfunction and may benefit from revascularization. Therapeutic interventions that improve dysfunctional but viable myocardium may significantly affect global LVEF, LV remodeling, and survival. The identification of CAD in patients with heart failure also has implications in secondary prevention strategies, as recurrent MI is a common mechanism of death in patients with heart failure.

Normal stress MPI in a patient with heart failure and LV dysfunction is highly predictive of the absence of CAD. Studies of MPI for detection of CAD in patients with LV dysfunction have shown high sensitivity but modest specificity (Fig. 16-40; see also Fig. 16-35).⁵¹ The modest specificity of MPI to rule out CAD is explained in part by pathologic and CMR studies⁷³ demonstrating patchy or larger confluent territories of fibrosis or scarring (see Chapter 17), manifested as fixed defects on SPECT MPI, in patients with nonischemic cardiomyopathy. Invasive studies as well as PET imaging have demonstrated attenuated coronary blood flow at rest and during hyperemic stress in nonischemic cardiomyopathy,¹⁸ which could be manifested as reversible defects.

Although the presence of any perfusion abnormality is not specific for ruling out CAD, the pattern of perfusion abnormality may assist in the differentiation between CAD and nonischemic etiology of heart failure. More extensive or more severe perfusion defects, or both, are more likely to represent CAD, whereas smaller and milder defects are more likely in patients with nonischemic cardiomyopathy.⁵¹

FIGURE 16-39 Iodine-123-labeled beta-methyl iodopentadecanoic acid (BMIPP) imaging of ischemic memory in a patient presenting to an ED with a suspected acute coronary syndrome. In the top row, short-axis (SA) tomograms demonstrate a significant lateral wall defect (arrows), suggesting prolonged posts ischemic suppression of fatty acid metabolism, referred to as ischemic memory. Horizontal long-axis (HLA) images (middle row) also demonstrate the defect (arrows), as does the polar map (bottom row). Subsequent angiography demonstrated a severe stenosis of the left circumflex coronary artery. (Modified from Kontos MC, Dilsizian V, Weiland F, et al: Iodoflucic acid 123 [BMIPP] fatty acid imaging improves initial diagnosis in emergency department patients with suspected acute coronary syndromes: A multicenter trial. *J Am Coll Cardiol* 256:290, 2010.)

Assessment of Myocardial Viability and the Potential Benefit of Revascularization

A goal in assessing viability is to optimize selection of patients with heart failure whose symptoms and natural history may improve after revascularization. Data suggest that hibernation and stress-induced ischemia are common in patients with stable heart failure, even in the absence of angina.⁷⁴ In a clinical trial in stable community-based patients with heart failure, of whom only a minority had angina, hibernation or stress-induced ischemia or both were demonstrated by SPECT imaging in approximately 50% of the subjects, suggesting that an important subpopulation of patients with heart failure may benefit from a noninvasive search for viability and ischemia.

The potential for decreased heart failure symptoms after revascularization correlates with the magnitude of the PET mismatch pattern (i.e., enhanced FDG uptake relative to perfusion).⁷ In a meta-analysis of outcome studies after viability imaging, patients with evidence of preserved myocardial viability⁷⁵ who underwent revascularization had a substantial reduction in the risk of cardiac death during

FIGURE 16-40 SPECT perfusion image demonstrating extensive severe fixed defects of the septum, apex, and inferior wall (arrows) suggestive of extensive previous myocardial infarction as well as extensive inducible ischemia of the lateral wall (arrowheads). This set of findings strongly suggests that CAD is the cause of the heart failure syndrome observed in the affected patient. HLA = horizontal long axis; SA = short axis; VLA = vertical long axis.

FIGURE 16-41 Data derived from a meta-analysis evaluating outcomes in patients with ischemic left ventricular dysfunction after viability testing. Among patients determined to have predominantly viable myocardium, treatment with medical therapy is associated with a 16% annual risk of cardiac death. Similar patients treated with revascularization have only a 3.2% annual risk of cardiac death, representing an 80% reduction in risk with revascularization. By contrast, patients with predominantly nonviable myocardium exhibit no difference in outcome whether they are treated with medical therapy or with revascularization. These data suggest that noninvasive interrogation of myocardial viability can identify treatment strategies associated with more favorable long-term outcomes. (Modified from Allman K, Shaw L, Hachamovitch R, Udelson JE: Myocardial viability testing and impact of revascularization on prognosis in patients with coronary artery disease and left ventricular dysfunction: A meta-analysis. *J Am Coll Cardiol* 39:1151, 2002.)

long-term follow-up compared with those patients treated medically (Fig. 16-41). Revascularization conferred no advantage in patients without substantial myocardial viability. These data suggest that non-invasive imaging of viability and ischemia can potentially play a role in selecting patients for revascularization, with the expectation of ameliorating symptoms and improving natural history. However, this analysis was based on 24 retrospective studies in which there may have been inadequate adjustment for comorbidity and in which the medical management would not be considered adequate in terms of current guidelines recommendations. For example, few if any patients received beta blockers in these cohort studies. This factor created the equipoise for the prospective STICH (Surgical Treatment of Ischemic Heart Disease) viability substudy, examining the influence of viability (determined by SPECT or dobutamine echocardiography) on outcomes associated with randomization to surgical or medical therapy.⁷⁶ In this study of more than 600 patients, viability status did not

influence the intervention effect on outcome. This may be due to better background medical therapies for patients with heart failure compared with those used in the older literature. On the basis of all of these data, current heart failure guidelines consider revascularization as a class IIa indication (level of evidence B) to improve survival in patients with mild to moderate LV systolic dysfunction and significant multivessel CAD or proximal LAD stenosis when viable myocardium is present.⁷⁷

Principles of Assessing Myocardial Viability by Radionuclide Techniques. The radionuclide tracers and techniques most often used to assess viability have been evaluated for their relation to preserved tissue viability by correlation of tracer uptake with histologically confirmed extent of tissue viability.⁷⁸ Quantitative analysis of tracer uptake correlates directly with the magnitude of preservation of tissue viability, and tracer uptake represents a continuous variable—that is, the magnitude of tracer uptake directly reflects the magnitude of preserved tissue viability. For a dysfunctional segment or territory, the probability of functional recovery after revascularization is related to the magnitude of tracer uptake, representing the degree of preserved myocardial viability (extent of hibernation or stunning) within that territory. A dysfunctional territory with normal or only mildly reduced tracer uptake thus has a high likelihood of improved function after revascularization. By contrast, a territory with a severe reduction in tracer uptake would represent predominant infarction, and the likelihood of improved function after revascularization would be low (Fig. 16-42). The magnitude of potential improvement of global LV function after revascularization is in turn determined by the extent of viable dysfunctional myocardium.

Imaging Protocols for Assessment of Myocardial Viability. ²⁰¹Tl: The presence of ²⁰¹Tl after redistribution implies preserved myocyte cellular viability. Because the absence of ²⁰¹Tl uptake on the redistribution images is not a sufficient sign of the absence of regional viability, however, iterations of the standard ²⁰¹Tl protocol have been investigated⁶ to optimize the assessment of regional viability (Fig. 16-43). After ²⁰¹Tl reinjection, approximately 50% of regions with fixed defects on stress-redistribution imaging show significant enhancement of ²⁰¹Tl uptake, predictive of improvement in regional LV function.⁷⁸ The presence of a severe ²⁰¹Tl defect after reinjection identifies areas with a very low probability of improvement in function.

Late redistribution imaging, 24 to 48 hours after the initial stress ²⁰¹Tl injection, allows more time for redistribution to occur and has good positive predictive value for improvement in function. Even with late redistribution imaging, the negative predictive value is suboptimal, because redistribution does not occur in some patients even after a prolonged period, and in addition, image quality may be poor.^{6,7} In such patients, ²⁰¹Tl reinjection after late redistribution imaging may provide further insight into defect reversibility and hence viability.

With rest-redistribution ²⁰¹Tl imaging, images are obtained 15 to 20 minutes after tracer injection at rest, reflecting regional blood flow at rest, and images obtained 3 to 4 hours after redistribution reflect preserved viability. The finding of a reversible defect at rest may identify areas of myocardial hibernation (see Fig. 16-43). This finding appears to be an insensitive although specific sign of potential improvement in regional function.^{6,79}

^{99m}Tc Sestamibi and Tetrofosmin: The performance of the ^{99m}Tc agents in predicting improvement in regional function after revascularization is similar to that of ²⁰¹Tl.⁷ Administration of nitrates to improve blood flow at rest before injection of sestamibi appears to improve slightly the ability of these tracers to detect myocardial viability.^{6,79}

PET Blood Flow-Metabolism Mismatch: The extent of the PET mismatch pattern (enhanced FDG uptake relative to blood flow; see Fig. 16-29) correlates with improvement in LV function after revascularization as well as with the clinical course, magnitude of improvement in heart failure symptoms, and survival after revascularization.^{6,15,79} Patients with heart failure and an extensive PET match pattern (diminished blood flow and severe reduction in FDG uptake), representing predominant infarction, are unlikely to benefit clinically from revascularization.

Comparison of Imaging Techniques for Viability Assessment. On the basis of a meta-analysis evaluating the ability of the various radionuclide techniques to predict improvements in regional function and EF, all of the radionuclide techniques (as well as low-dose dobutamine echocardiography; see Chapter 14) perform in a relatively similar manner regarding positive and negative predictive values

FIGURE 16-42 Relation between tracer uptake in a dysfunctional territory and the subsequent probability of functional recovery after revascularization. The probability of improved regional left ventricular function after revascularization is significantly related to the quantitative degree of tracer uptake. **Upper right**, SPECT image from a patient with a large, severe defect in the anterior and apical walls. The severity of the defect suggests that significant functional recovery would not be expected with revascularization. **Upper left**, SPECT image showing extensive myocardial viability in a patient with left ventricular dysfunction (ejection fraction 30%) and severe three-vessel coronary disease. Substantial tracer uptake is evident throughout the anterior wall and apex (*arrow*), territories with significant regional dysfunction. The significant tracer uptake suggests extensive myocardial (myocyte) viability and high probability of functional recovery after revascularization. (Modified from Bonow RO: *Assessment of myocardial viability with thallium-201*. In Zaret BL, Beller GA [eds]: *Nuclear Cardiology: State of the Art and Future Directions*. St. Louis, Mosby, 1999, pp 503-512; and Udelson JE: *Assessment of myocardial viability with technetium-99m-labeled agents*. In Zaret BL, Beller GA [eds]: *Nuclear Cardiology: State of the Art and Future Directions*. St. Louis, Mosby, 1999, pp 513-533.)

FIGURE 16-43 Rest-redistribution thallium imaging performed as part of a dual-isotope technetium-thallium stress imaging protocol in a 55-year-old patient with severe heart failure and left ventricular dysfunction (ejection fraction 30%). The initial thallium images at rest demonstrate several areas of reduced blood flow at rest involving the septum, anteroapical wall, and inferior wall. Thallium redistribution imaging 4 hours later demonstrates substantial redistribution of thallium in the septal, anteroapical, and inferior regions of the left ventricle, indicating myocardial viability, with only the basal portion of the inferolateral wall representing irreversibly damaged myocardium. After the thallium redistribution image acquisition, stress imaging with ^{99m}Tc -sestamibi demonstrates inducible ischemia in the septum and anterior wall. However, without the redistribution images, routine stress-rest imaging would have given misleading information about viability because of the apparently irreversible defects in the inferior and anteroapical walls. (From Holly TA, Bonow RO: *Assessment of myocardial viability with thallium-201 and technetium-based agents*. In Zaret BL, Beller GA [eds]: *Nuclear Cardiology: State of the Art and Future Directions*. 4th ed. Philadelphia, Mosby, 2010, pp 594-607.)

for improvements in regional function.⁷⁵ SPECT techniques appear to be slightly more sensitive, dobutamine echocardiography appears to be slightly more specific, and PET techniques appear to have better accuracy. A randomized trial of patients with moderate LV dysfunction being considered for revascularization randomly allocated to have viability information supplied by either PET imaging or SPECT stress-rest sestamibi imaging found no difference in outcomes during long-term follow-up.⁸⁰

In a randomized trial of PET versus standard care in guiding management in patients with LV dysfunction, a trend was observed toward improved outcomes with PET-guided management.⁸¹ For those patients in the trial whose clinicians adhered to the PET-directed management recommendations, outcomes were significantly better. As noted previously, a meta-analysis of observational outcome studies related to myocardial viability demonstrated no difference among the techniques commonly used to assess viability (PET versus SPECT versus dobutamine echocardiography) with regard to reduction of mortality after revascularization (see Fig. 16-41).⁷⁵

All of these data suggest that differences between the imaging approaches to assess viability are small, and that choice of modality should be driven by the available expertise and experience. For patients with more severe LV dysfunction, in whom thinner myocardial walls often are seen, a theoretical advantage of PET and CMR is their better spatial resolution for imaging thinner objects.

Selection of Patients with Heart Failure for Viability Assessment

Guidelines recommend that patients with heart failure and active angina benefit from revascularization and thus should be referred directly for angiography.⁷⁷ In some situations, subsequent noninvasive definition of regional viability and ischemia may be important to plan the revascularization strategy when the anatomy is known.

For patients with heart failure and no angina, studies suggest that ischemia and viability may be present in a significant proportion of such patients,⁷⁴ who have potential benefit from revascularization. For most such patients with heart failure, a search for underlying ischemia and viability would be an appropriate clinical strategy at some point in their evaluation.⁵⁷ The imaging data can be used in decision making to help balance the risks and benefits of revascularization in a patient with heart failure and LV dysfunction by supplying information on potential benefit of a revascularization strategy.

Assessment of Left Ventricular Function in Heart Failure

For patients with the clinical syndrome of heart failure, the distinction between those with preserved and those with impaired systolic function has important clinical relevance. Clinical trials evaluating the use of such therapeutic agents as ACE inhibitors, angiotensin receptor blockers, and beta blockers have focused on the subpopulation of heart failure patients with impaired systolic function (see Chapter 25).⁷⁷ Thus accurate determination of LV function in a patient with heart failure defines the evidence-based therapeutic approach that should be undertaken.

On the basis of the quantitative and reproducible nature of the EF results, equilibrium RVG techniques have been used in large clinical trials to identify systolic dysfunction.^{7,79} In contemporary practice, ECG-gated SPECT is often used for determination of systolic function. The simultaneous assessment of LV systolic function as well as stress and rest perfusion by gated SPECT MPI can provide a range of information relevant to the care and clinical decision making for patients with heart failure, including the state of LV function, the probability of CAD as the cause of heart failure, and the presence and extent of viability and ischemia.

Imaging in Inflammatory and Infiltrative Cardiomyopathies

Myocarditis

Inflammatory injury to the myocardium by infective agents, postinfective immune processes (e.g., Chagas disease, rheumatic carditis), hypersensitivity, and autoimmune conditions can cause myocardial dysfunction. The clinical manifestation of such an inflammatory process is acute myocarditis and cardiac allograft rejection (see

Chapters 28 and 67). Because myocyte necrosis is an obligatory component of myocarditis (cellular infiltrates, predominantly lymphocytes and macrophages, clustered around necrotic myocytes), ¹¹¹In-labeled antimyosin antibody, which specifically targets myosin heavy chain, has been used for the detection of necrosis associated with myocarditis and heart transplant rejection. In patients with biopsy-positive myocarditis, the sensitivity of an antimyosin scan is approximately 95%, with a negative predictive value of approximately 95%. However, the specificity and positive predictive value of antimyosin imaging are modest, in the 50% range.⁸²

Sarcoid Heart Disease

Cardiac involvement occurs in approximately 20% of patients with sarcoidosis (see Chapter 65). In patients presenting with advanced AV block, SPECT MPI or gallium-67 imaging (a nonspecific indicator of inflammation) along with CMR or CT can localize myocardial involvement of sarcoidosis.⁷ Focal fibromuscular dysplasia found in the small coronary arteries may provide an explanation for focal ischemic injuries and reversible defects described on myocardial perfusion SPECT. LV perfusion defects have been associated with AV block and heart failure, and RV defects have been associated with ventricular tachycardia of RV origin.⁸³

FDG PET imaging (with or without anatomic colocalization with CT or CMR) has gained interest for diagnosis and potential follow-up of cardiac sarcoidosis.⁸⁴ Because inflammatory cells, such as macrophages, contain increased membrane glucose transporters and exhibit significantly high hexose monophosphate shunt pathway activity, FDG can accumulate within areas of granulomatous inflammation and cannot diffuse out or be metabolized further. As a granuloma matures, the number of macrophages and inflammatory cells decreases, with subsequent fibrous replacement. Although CMR typically displays myocardial enhancement with delayed gadolinium enhancement in regions of myocyte replacement fibrosis (see Chapter 17), the CMR signal alone may not be able to differentiate areas of acute from chronic or mixed cardiac sarcoidosis.⁸⁵ On the other hand, FDG PET imaging in concert with either CMR or CT may be optimal for monitoring the efficacy of therapy directed at the active inflammation in cardiac sarcoidosis and for detection of recurrence.

Cardiac Amyloidosis

Cardiac amyloidosis (see Chapter 65) involves the deposition of amyloid fibrils into the myocardium, which leads to impaired relaxation. Patients with amyloidosis may demonstrate abnormally prolonged LV diastolic filling and an increased atrial contribution to total diastolic filling. ^{99m}Tc-pyrophosphate scintigraphy may be useful to identify patients with cardiac amyloidosis, demonstrating diffuse uptake throughout the myocardium, and may help to noninvasively differentiate deposition due to light chain amyloid from the transthyretin-related variant.⁸⁶

Assessment of Cardiac Sympathetic Innervation in Heart Failure

An emerging area of risk stratification involves the use of ¹²³I-meta-iodobenzylguanidine (¹²³I-MIBG) imaging of cardiac sympathetic innervation in heart failure. ¹²³I-MIBG shares its reuptake mechanism and endogenous presynaptic storage with norepinephrine. ¹²³I-MIBG is taken up into presynaptic terminal via uptake-1, but as a false neurotransmitter ¹²³I-MIBG is not catabolized, thereby localizing in high concentration in nerve terminals allowing for external imaging. The highest density of sympathetic nerves is in the RV and LV myocardium, which can be imaged with single-photon-emitting radiotracer ¹²³I-MIBG, or positron-emitting radiotracers such as ¹¹C hydroxyephedrine and ¹⁸F-fluorobenzylguanidine.⁸⁷ PET provides higher resolution images than planar or SPECT imaging with ¹²³I-MIBG, allowing for regional analysis of the innervation signal and kinetic modeling for true quantification.

In the post-MI setting, the territory of abnormal ¹²³I-MIBG uptake often exceeds the final infarct size, and such patients are at higher risk for subsequent ventricular arrhythmias.^{51,88} In two multicenter prospective phase 3 studies comprising more than 900 patients with heart failure and systolic dysfunction, 2-year event-free survival was significantly higher for those patients with more preserved ¹²³I-MIBG

uptake than for patients who showed evidence of more advanced functional denervation on ^{123}I -MIBG imaging.⁸⁹ ^{123}I -MIBG uptake was quantified using the ratio of counts/pixel in whole-heart (H) and in upper mediastinum (M) regions in 4-hour delayed anterior planar images of the chest (Fig. 16-44). Adverse events were defined as symptomatic progression, potentially life-threatening arrhythmic event, or cardiac death. Two-year event-free survival was 85% in subjects with more preserved ^{123}I -MIBG uptake (H/M ratio ≥ 1.6), compared with 63% in subjects with an abnormal imaging result (H/M < 1.6 ; hazard ratio [HR]: 0.40; $P < .001$). These findings contributed to FDA approval of ^{123}I -MIBG for imaging sympathetic innervation of the myocardium in patients with heart failure, to assess risk of adverse outcomes. Additional clinical studies may define the role of this agent in optimizing selection of post-MI patients or those with heart failure who may (or may not) benefit from a defibrillator, as well as in predicting inducibility of ventricular arrhythmias (see Chapters 26 and 36).⁹⁰

Imaging to Assess Risk Before Noncardiac Surgery

The clinical role of MPI for evaluation of patients before elective noncardiac surgery (see Chapter 80) is important in selected cases, because CAD constitutes a major perioperative and long-term risk in such patients. The ischemic burden from the stress of surgery and postoperative recovery can result in MI or cardiovascular death. Prospective identification of such patients has important prognostic and preventive implications.

Initial cardiac assessment of patients undergoing noncardiac surgery should be based on (1) the urgency of the surgery (2) the presence/absence of any active cardiac conditions, such as decompensated heart failure, (3) the type of surgical procedure (low-, intermediate-, or high-risk) and the institutional event rate, and (4) the

patient's functional capacity.⁹¹ Surgical procedures classified as high-risk procedures (cardiac event risk greater than 5%) include major vascular surgery.

For patients having non-low-risk surgery who also have limited or unknown functional capacity, current guidelines recommend imaging for risk stratification based on "revised cardiac risk index" factors, which include history of CAD, previous heart failure, diabetes, renal insufficiency, and cerebrovascular disease.⁹¹ Noninvasive testing may be considered in patients with such risk factors for perioperative events, if it will change management. Asymptomatic patients with known CAD who have had revascularization within the past 5 years generally require no further evaluation.⁹¹

Normal MPI using pharmacologic stress uniformly predicts a low likelihood (approximately 1%) for perioperative or longer-term postoperative cardiac events.⁹¹ Reversible perfusion defects predict an increased risk of cardiac events, and the magnitude of risk is related to the extent of ischemia. Although fixed perfusion defects (infarct) portend a lower risk than ischemia for perioperative cardiac events, the risk is higher than that with a normal scan, and patients with infarct or LV dysfunction are at higher long-term risk for death or heart failure.⁹¹

In clinical practice, most patients in whom extensive ischemia is demonstrated preoperatively undergo catheterization with expectation of revascularization. Clinical trial evidence supporting this practice provides conflicting evidence,^{92,93} however, and the threshold of ischemia extent above which revascularization might reduce short- or long-term cardiac risk is not known. In the contemporary era of PCI, the potential need for prolonged dual antiplatelet therapy after stenting also must be factored into the complex benefit-risk ratio in considering whether to pursue stress testing and potential catheterization with subsequent revascularization.

FIGURE 16-44 Examples and quantification of I-123 MIBG imaging of cardiac sympathetic innervation. In these anterior planar images, the area of the heart is denoted by the arrows. **A**, Normal cardiac uptake of MIBG, with uptake in the heart clearly greater than in the lungs and mediastinum. **B**, Abnormal uptake, similar to that in the lungs or mediastinum. **C**, Apparent absence of cardiac uptake, consistent with severe functional denervation. **D**, The method for quantification of MIBG uptake is demonstrated. A region of interest (ROI) is drawn around the cardiac epicardial border, and a region within the mediastinum, and a ratio of the counts/pixel in the heart ROI and the mediastinal ROI (the H/M ratio) is calculated. (Modified from AdreView Prescribing Information. <http://dailymed.nlm.nih.gov/dailymed/lookup.cfm?setid=c89d3ecc-4f4c-4566-8808-79152344194d>. December 13, 2013.)

MOLECULAR IMAGING OF THE CARDIOVASCULAR SYSTEM

During the past several decades, radionuclide cardiac imaging has focused primarily on “organ-level” assessment of physiology and pathophysiology, such as myocardial perfusion and ventricular function. However, advances in radiochemistry and imaging technology have enabled the interrogation of many more processes at the cellular and molecular level. Such techniques have the potential to refine the current understanding of mechanisms involved in cardiovascular diseases, such as instability of atherosclerotic plaque in an individual, with the promise of more targeted individualized therapy.

Imaging of Potentially Unstable Atherosclerotic Plaque and Platelet Activation

Vulnerable atherosclerotic plaques typically have a necrotic lipid core with a thin fibrous cap and large amount of macrophages (see Chapter 41). When such vulnerable plaques rupture, they cause MI, sudden death, or stroke. Thus the biologic composition and inflammatory state of an atherosclerotic plaque, rather than its size or degree of luminal stenosis, may be the major determinants of acute clinical events.⁹⁴ Hence development of noninvasive imaging techniques that target plaque inflammation and other processes leading to plaque vulnerability is an area of intense investigation.⁹⁵

Studies have demonstrated the clinical feasibility of direct visualization and characterization of coronary and carotid artery plaques with PET imaging. Coronary lesions that are vulnerable to rupture display pathologic features, such as inflammation, intraplaque neovascularization, microcalcification, apoptosis, and intraplaque hemorrhage, that potentially can be targeted with molecular imaging agents. Moreover, microcalcifications in thin fibrous caps increase the risk of plaque rupture related to stress-induced microfractures around the calcifications, which can lead to acute coronary thrombosis.

Accordingly, recent studies have focused on noninvasive molecular imaging probes that target plaque composition, such as inflammation and/or microcalcification, using PET-CT technology. ¹⁸F-FDG is an excellent probe to target macrophage infiltration as a marker of plaque inflammation, and another molecular probe, ¹⁸F-sodium fluoride (¹⁸F-NaF), targets active microcalcifications in atherosclerotic plaques.⁹⁶ Correlative studies between arterial plaque inflammation (by ¹⁸F-FDG), active mineral deposition (by ¹⁸F-NaF), and vascular calcification (by CT) in major arteries (aorta and its major branches including carotid) have shown the ability of these two molecular probes to visualize these distinct biological processes in an atherosclerotic plaque.⁹⁷ The feasibility of ¹⁸F-NaF PET for the detection of coronary microcalcification in humans was shown in a prospective cohort of healthy volunteers and patients with aortic sclerosis and stenosis.⁹⁸ Coronary ¹⁸F-NaF uptake was higher in patients with coronary atherosclerosis than the control subjects, and correlated with the CAC score. Similarly, in a study of patients with recent MI and those with stable angina, the highest coronary ¹⁸F-NaF uptake was observed in the culprit plaque compared with the nonculprit plaque in the patients with recent MI⁹⁹ (Fig. 16-45). Among those with stable angina, almost half of the patients had plaque with focal evidence of increased ¹⁸F-NaF uptake, and these plaques had more high-risk features of plaque vulnerability on intravascular ultrasound (see Chapter 20) than plaques without ¹⁸F-NaF uptake. These data suggest the potential of imaging to identify plaques and patients at risk of future ACS, paving the way for prevention trials.

The integrin $\alpha\beta 3$, which has been investigated for tumor neovascularization, also plays an important role in plaque vasa vasorum neoangiogenesis. An ¹⁸F-labeled PET radiotracer that images

FIGURE 16-45 Uptake of ¹⁸F-NaF in high-risk atherosclerotic plaque. **A**, The arrow indicates the site of an acute occlusion of the proximal left anterior descending artery in a patient with STEMI. **B**, PET-CT imaging performed several days later demonstrates intense focal uptake of the tracer at the site of the plaque (arrow), consistent with high-risk plaque features. (Modified from Joshi NV, Vesey AT, Williams MC, et al: ¹⁸F-fluoride positron emission tomography for identification of ruptured and high-risk coronary atherosclerotic plaques: A prospective clinical trial. *Lancet* 383:705, 2014.)

$\alpha\beta 3$ -integrin expression (¹⁸F-galacto-RGD) targets both macrophages and intraplaque neovascularity (both implicated in progression and rupture of atherosclerotic lesions) that may be directly involved in the degradation of the protective fibrous cap of atherosclerotic plaques.¹⁰⁰ Whether this agent can ultimately be used to evaluate atherosclerotic lesions in patients remains untested.

It is important to recognize that most of the studies using these molecular imaging probes for atherosclerosis are restricted to larger arterial beds such as those for the carotid arteries and aorta, rather than the coronary arteries. Owing to the limitations of the partial volume effect of small plaques, low target-to-background ratio of tracer uptake, and cardiac motion, direct visualization of atherosclerotic plaques in coronary arteries with current PET-CT technology is challenging.^{95,96} Whether molecular imaging of noncoronary vascular beds is useful in predicting coronary plaque rupture and acute MI has not been ascertained. If successful, such molecular probes could provide new insights into the complex development and progression of atherosclerosis, facilitate current understanding of mechanisms of plaque rupture, stimulate development of new medications to prevent and/or regress atherosclerosis, and provide a noninvasive tool to monitor the treatment effect.

Imaging of Apoptosis

An approach to evaluation of patients with LV dysfunction after MI is the visualization of apoptosis, or programmed cell death, using ^{99m}Tc-labeled annexin V, which localizes to apoptotic cells.¹⁰¹ In one study, positive uptake of this agent was seen in six of seven post-MI patients, localized to areas of perfusion defects at rest.¹⁰² Such findings for this agent may herald the ability to track this process noninvasively in syndromes such as heart failure and to study approaches to attenuate the unfavorable pathophysiology of apoptosis.

Imaging of Cell- or Gene-Based Regenerative Therapy

Stem and progenitor cells have the ability to self-renew and the potential for multilineage differentiation (see Chapter 30). Local targeted gene delivery or implantation of skeletal myoblasts, bone marrow-derived stem cells, mesenchymal stem cells, circulating progenitor cells, embryonic stem cells, or cardiac resident cells may functionally revitalize scarred, noncontractile myocardial regions. These properties offer the potential for use in regenerative therapies and cardiac repair. Clinical trials to date, however, have demonstrated only marginal benefits of cell-based therapy in ischemic cardiomyopathy and chronic heart failure and after acute MI.^{103,104}

FIGURE 16-46 Cardiac micro-PET images, in short-axis (SA), vertical long-axis (VLA), and horizontal long-axis (HLA) views, of a rat heart transplanted with cardiomyoblasts expressing a PET reporter gene. The gray-white uptake represents homogeneous perfusion by ^{13}N -ammonia, and the color uptake in the lateral wall represents the viable transplanted cardiomyoblasts studied in vivo (**bottom row**). There is no uptake in the control heart, which demonstrates normal perfusion (**top row**). (Modified from Wu JC, Chen LY, Sundaresan G, et al: Molecular imaging of cardiac cell transplantation in living animals using optical bioluminescence and positron emission tomography. *Circulation* 108:1302, 2003.)

Molecular imaging tools that can identify the optimal cell type, delivery route, dosing regimen, and timing of cell delivery may be the key to understanding and advancing cardiac stem cell therapy.¹⁰⁵ This dual goal can be accomplished by direct labeling of the therapeutic cells (such as $^{99\text{m}}\text{Tc}$ or ^{111}In radionuclides) or reporter gene imaging that allows observation of intracellular or genomic events by PET, SPECT, PET-CT, or optical imaging. An alternative approach is labeling cells with iron oxide nanoparticles for CMR. Noninvasive assessment of the fate of myogenic cell grafts and therapeutic genes in vivo may provide insight into the mechanism by which they improve cardiac function or prevent remodeling. In animal studies, transplanted cardiomyoblasts expressing a PET reporter gene have been imaged longitudinally to gain insight into the pattern of cell survival.¹⁰⁵ With use of cardiac micro-PET imaging, detailed tomographic locations of transplanted cells were obtained (**Fig. 16-46**). In an experimental mouse model of MI that included intramyocardial injection of human cardiac progenitor cells, initial cell retention assessed by cardiac micro-PET predicted long-term myocardial functional improvement by CMR¹⁰⁶ (**Fig. 16-47**). Such molecular imaging techniques that track and localize stem cells may provide the future tools to elucidate fully the equivocal results achieved in stem cell therapy in human trials.

Imaging of Interstitial Fibrosis and Left Ventricular Remodeling

Activation of the renin-angiotensin-aldosterone system (RAAS), particularly its autocrine and paracrine components within the tissues, occupies a central place in the pathogenesis and progression of LV remodeling, interstitial fibrosis, and heart failure (**see Chapter 22**). Myocardial fibrosis in chronic heart failure is a dynamic process that is determined by a balance between collagen synthesis and its

degradation by matrix metalloproteinases. In addition, local tissue synthesis of aldosterone appears to be mainly angiotensin II (Ang II) driven and may participate in a positive feedback loop, because aldosterone upregulates the angiotensin type 1 receptor (AT1R) and ACE expression in cardiac cells.

Investigations in animal models and also in human subjects have shown that radionuclide imaging of the RAAS may offer a more direct assessment of RAAS activation. Such an approach has been used in experimental systems to study the human tissue ACE and AT1R directly. Use of ^{18}F -fluorobenzyl-lisinopril in human explanted hearts has shown a relationship between ACE and collagen replacement, because ACE was absent in the collagen-stained areas and was increased in the juxtaposed areas of replacement fibrosis.¹⁰⁷ These data suggest that increased ACE may be a stimulus for collagen replacement and remodeling. A subsequent study with $^{99\text{m}}\text{Tc}$ -lisinopril in transgenic rats overexpressing human ACE-1 established the specificity of the radioisotope probe to myocardial ACE-1 and demonstrated close correlation between quantitative uptake of $^{99\text{m}}\text{Tc}$ -lisinopril and enzyme activity.¹⁰⁸ Moreover, the signal intensity was sufficiently high to allow external imaging by hybrid micro-SPECT-CT (**Fig. 16-48**). Recently, the AT1R receptor also was targeted for imaging the human heart.¹⁰⁹ This first-in-human application of receptor ligand ^{11}C -KR31173 combined with PET-CT confirmed the presence of local tissue RAAS in human hearts, proved to be safe and showed that the signal was high enough to allow external imaging with PET. However, the myocardial retention of KR31173 was significantly lower in these healthy human subjects than that observed in normal healthy pigs, with a limited specificity: Only 54% of the signal targeted the AT-1 receptor.^{109,110}

In the future, noninvasive radionuclide imaging in patients with heart failure may allow monitoring of changes in ACE expression patterns in vivo, possibly reflecting progression of disease and the effect of therapies before collagen replacement ensues.

Imaging of Cardiac Valvular Inflammation and Calcification

Beyond imaging vascular atherosclerosis, FDG and ^{18}F -NaF techniques also may identify patients with early valvular inflammation and microcalcification, before progression to severe, calcified stenosis is detectable by echocardiographic and CT imaging (**see Chapter 63**). In oncology patients with echocardiography-defined degenerative

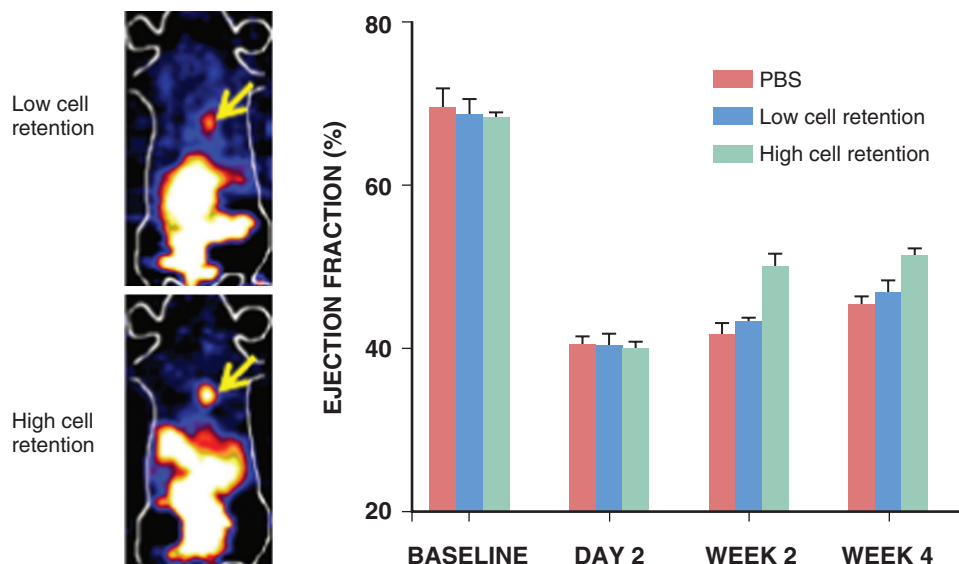

FIGURE 16-47 Early cell retention identified by molecular imaging predicts long-term myocardial functional improvement. Mice underwent experimental myocardial infarction followed by intramyocardial injection of human cardiac progenitor cells expressing a mutant thymidine kinase reporter gene tagged to a PET radionuclide. Serial PET and CMR studies were later performed to assess cell engraftment and left ventricular function. **Left**, A representative coronal PET image is shown for a mouse with low cell retention on day 1 (**top**), compared with that of a mouse with high cell retention (**bottom**). **Right**, The average CMR-derived EF is greater at both weeks 2 and 4 for the mouse cohort with high initial cell retention than for the cohort with low cell retention or injection of placebo solution (PBS). (Modified from Liu J, Narsinh KH, Lan F, et al: Early stem cell engraftment predicts late cardiac functional recovery: Preclinical insights from molecular imaging. *Circ Cardiovasc Imaging* 5:481, 2012.)

aortic stenosis who had undergone FDG PET-CT, the relationship between aortic valve inflammation and stenosis was investigated at the leaflet coaptation point.¹¹¹ Patients with mild and moderate aortic stenosis by echocardiography or calcification on CT had significantly increased aortic valve FDG signal compared to controls. Patients with severe aortic stenosis or calcification did not show increased FDG signal, suggesting an end stage of the inflammatory process. In a subset of patients with serial echocardiographic studies over a 1- to 2-year period, 82% of the subjects who exhibited high FDG valve signal intensity demonstrated progression of aortic

stenosis, compared with only 22% of the subjects with low FDG signal intensity.¹¹¹ This observational study suggests a potential role for FDG PET-CT in identifying patients at risk for more rapid progression of aortic stenosis.

In a subsequent study, in which both FDG and ¹⁸F-NaF were administered to assess valvular inflammation and calcification, 91% of patients with aortic stenosis exhibited increased ¹⁸F-NaF uptake.¹¹² The correlation between the degree of aortic stenosis and the PET signal was significantly higher with ¹⁸F-NaF than with FDG, suggesting different biologic processes of inflammation and microcalcification during the progression of valvular stenosis.

FIGURE 16-48 Noninvasive micro-SPECT-CT imaging of angiotensin-converting enzyme (ACE)-1 activity. **Top row**, Micro-SPECT-CT imaging provides simultaneous scintigraphic and morphologic localization of ^{99m}Tc-labeled lisinopril uptake, 60 minutes after tracer administration, in a control animal (left) and in an ACE-1-overexpressing transgenic animal (right). White arrowhead demonstrates intense lung uptake, and yellow arrows point to myocardial ACE-1 activity. The ACE-1-overexpressing model shows much higher-intensity uptake in the myocardial region. **Bottom row**, The micro-SPECT data are superimposed on CT data for better myocardial localization in the overexpressing model. (Modified from Dilsizian V, Zynda TK, Petrov A, et al: Molecular imaging of human ACE-1 expression in transgenic rats. *J Am Coll Cardiol Img* 5:409, 2012.)

Imaging of Cardiac Device and Prosthetic Valve Infections

Cardiac Device Infection

There has been significant increase in cardiac device implantation worldwide, which has been accompanied by an increase in the absolute number of device infections (see Chapter 64). It has been reported that the all-cause 12-week mortality rate could be as high as 35% with cardiac device infection, especially for those with methicillin-resistant *Staphylococcus aureus* infection.¹¹³ The 1-year mortality after removal of an infected device has been reported as 12% in patients with pocket infections and 17% in those with endovascular infections.¹¹³ Accurate diagnosis of cardiac device infection is therefore critical for clinical decision making such as use of antibiotic therapy alone or device extraction but represents a challenge with currently available methods. Among patients with suspected cardiac implantable pacemaker or defibrillator infections, FDG PET-CT can accurately localize the site and extent of the infection.¹¹⁴ A potential advantage of FDG PET-CT is in its detection of inflammatory cells early in the infection process, before morphologic damage ensues.¹¹⁵ In contrast with its reported high accuracy in detecting cardiac device pocket infection, FDG PET-CT appears to be less reliable for lead infection or vegetation evaluation, which may be attributed to the small size of the lead and vegetation, and/or ongoing antibiotic treatment.¹¹⁶

Cardiac Prosthetic Valve Infection

Nearly half of prosthetic valve endocarditis cases are complicated by periannular extensions and need urgent surgical intervention (see Chapter 64).¹¹⁷ Transesophageal echocardiography (TEE) may fail to recognize this potentially fatal complication. Although ECG-gated CT angiography can improve the diagnostic accuracy in some cases (see Fig. 64-4), it also is a purely anatomic technique. The incremental value of FDG PET-CT to the findings on TEE or CT angiography has been shown in observational case series (Fig. 16-49).¹¹⁸ Although

FIGURE 16-49 Periannular prosthetic valve endocarditis detected by FDG PET. A patient with a bileaflet mechanical prosthetic aortic heart valve (PHV), placed 20 years earlier, presented with fever and blood cultures positive for *S. aureus*. Despite a high degree of clinical suspicion for endocarditis, findings on transthoracic echocardiography and TEE, as well as CT (A), were unremarkable for evidence of infection. B, FDG PET-low-dose CT fused image revealed high uptake around the aortic PHV (arrows), near the proximal right coronary artery (RCA). C, Subsequently, CT revealed a mycotic aneurysm beneath the RCA origin, confirmed by urgent operation. In this case, only FDG PET-CT detected these abnormalities at a very early stage. LCA = left coronary artery. (A, B, Modified from Tanis W, Scholtens A, Habets J, et al: Fusion of cardiac computed tomography angiography and ¹⁸F-fluorodesoxyglucose positron emission tomography for the detection of prosthetic heart valve endocarditis. *J Am Coll Cardiol Img* 6:1008, 2013.)

these results are encouraging, FDG PET-CT is not advocated as a "first-line" or confirmatory imaging study for detecting prosthetic valve endocarditis.¹¹⁹ Rather, it should be reserved for patients with clinical and microbiologic suspicion of endocarditis but indeterminate or negative TEE findings.
